Repot the plants before they become root-bound, and as the season advances, and the temperature outside becomes milder, gradually give more and more ventilation, for upon a cool and airy atmosphere a great deal of success in Begonia-culture depends. Low span-roofed houses give most satisfaction. The soft and watery tissue of Begonias soon responds to favorable or unfavorable conditions; therefore let them have a house to themselves where possible, and no make-shift permitted. The smaller plants may be grown on the side shelves on ashes or cocoanut-fibre, while the larger and taller specimens may be elevated on shelving, staging tier above tier in the centre of the house and near the glass. A free play of air among the foliage keeps it fresh and healthy, and a dry atmosphere prevents the spotting of either flowers or foliage, as the weather gets warm about April and onwards. More or less shading during the heat of the day will be required after that month. When the plants have finished flowering or become useless for decorative purposes, stand them out-of-doors, in a sunny position, but sheltered from wind, and keep them watered till the leaves show signs of decay, after which water may gradually be withheld till the tubers ripen and the stems drop away. Remove them indoors on the approach of frosty nights.

Tuberous Begonias as Bedding-plants.

THESE new-comers, which have so greatly pleased us the past three years, have been disappointing this season, though not from any fault of their own, or not from any cause that will impair their usefulness in the future. The trouble is that their true character has not been recognized. The enthusiastic grower has claimed too much for them when he asserts that they can be grown in the same manner as the *Gladiolus*, and that the tubers can be kept dry and planted out when and where wanted just as the *Gladiolus* can. This mistake has cost many amateurs a good many plants, and has made them cautious about buying, and in some cases has quite discouraged them. This should not be, as the plant is all that has been claimed for it, and more.

The past year, it is true, has been a hard one for the Tuberous Begonia, as it has been for almost every other plant. Heat and moisture have not been proportionate. But the present season has only proved to us that this plant is not injured by hot weather, as is shown by the display made when it is grown on a large scale. Although the losses in the nursery have been considerable, they have been of great value in the line of practical knowledge. The lesson learned is, that it must be treated as a bedding-plant, and as such must have a good start in the greenhouse, and not transferred to the border until in a thrifty, growing state. The plants should be from four to six inches high, and proportionately strong when set out; then, even in a season like the present, they have no rivals. Those put out in Mr. Griffin's nursery this season, when well started, are marvels of beauty and healthfulness; they do not show in the least the effects of a drought or of heat. Those that were too young, and but little started, have suffered badly. The same is shown plainly in many other places, proving most conclusively that this plant has come to stay, and that it far surpasses anything we have in the way of low-growing bedding-plants, and, further, that to grow it successfully, plants, strong and well grown, must be put out, rather than dry tubers.

Floral Park, N. Y.

Planting Perennials.

MANY persons are now inquiring as to the best time to plant hardy herbaceous plants, and as the season is here when the operation may safely be carried out a few notes on the general subject will be timely. It has been stated that all hardy plants may be planted in spring, and the inference is that that is the best season to transplant. This is true with regard to shallow-rooting plants or those which are of small size when fully developed, but the trouble is, that in all gardens, large or small, the arrival of spring inevitably brings with it a rush of work peculiar to the season, and when this is completed many of the earliest border-plants are already well advanced, perhaps more so elsewhere than in our own gardens, and this adds to the risk of procuring them in spring. Last fall we found that Elm-roots had complete possession of a large border here, and at this season the whole of the plants were lifted, the border dug two feet deep and enriched, and the plants moved over as the work proceeded, and not a plant was lost. The season was a favorable one; the roots took hold at once, and when frost came the plants were well established. This spring we had six weeks of dry weather without a shower

after snow left, and had the work been done then many losses and a poor display would have been the result. It is a safe rule, therefore, not to put off until spring what may be done in fall.

Where alterations are contemplated in existing arrangements this is the best time to make a survey while the plants are in character. Strong-growing plants will be aggressive and exclude weaker ones, and attention to such matters should be given every year. Some plants, too, will die out from various causes. Seasons differ. A wet year suits some plants to the injury of others, and vice versa, and if this should chance to be an unfavorable time to make changes and supply losses, take notes of the situation so that the necessary changes can be made before growth commences next year. Up to this time we have had no frost, but as soon as the garden has been seared by it the plants that are herbaceous will be cut down, divided if necessary and replanted and the whole borders treated to a liberal top-dressing of well-decayed compost, which will remain on in spring and not be dug in. The annual digging and cleaning of hardy flower-beds requires skilled labor of the best kind to avoid injury to the dormant plants. Therefore the borders are left alone after the top-dressing in fall, and they look, to the well-informed, snug and comfortable.

The operation of planting means more than making a hole in the ground and thrusting the roots into it. Plants hold out in dry weather by means of their deep roots, and the proper way to plant is to take a spade and loosen the soil thoroughly over as large a space as the foliage should cover when fully developed. We should remember that the parts of a plant above and below the soil are beautifully balanced by nature, and if the one cannot develop the other will not.

There are always in the border plants that are more or less tender and which require lifting to protect them in winter. These should now be taken up and the roots placed in soil in a cool cellar. Plants keep better in such a place than in a frame outdoors. *Tritonias* (*Kniphofias*), *Montbretias*, *Arundo donax*, *Pampas Grass*, *Eulalias*, *Helianthus multiflorus*, *Melanthus major*, *Conoclinium cœlestinum*, *Hibiscus coccineus*, and possibly the Japan *Anemones*, which are sometimes winter-killed with us, are better for this treatment. This lifting of plants is not altogether an unmixed evil, for it gives an opportunity to have fresh combinations each season, and in this way monotony is avoided. *Pennisetum longistylum*, a most elegant Grass, is now at its best. A recent writer in GARDEN AND FOREST spoke of it as an annual; it is as much a perennial as the *Eulalias* or *Arundo*, but requires lifting in fall. Our clumps were stored in the cellar last winter and are much larger than seedlings would be.

It remains now to note what not to plant at this season. For the most part all prostrate plants should be set out in spring, such as *Gypsophila repens*, *Veronica repens*, *Arenarias*, *Arabis*, *Sedums*, varieties of *Phlox subulata*, *Myosotis*, dwarf *Silenes*, *Lychnis* and *Campanulas*, all ornamental grasses, *Hollyhocks*, *Anemone Japonica* and *Hellebores* of all kinds. Prostrate plants do not take hold so readily in fall as deeper-rooting kinds, and they cannot be mulched so safely to prevent heaving by frost when they are planted late and not protected. All plants of doubtful hardiness should be set out in spring; all of the above-named list belong to one of these sections. By fall planting I do not mean November planting, but planting as early as possible now, before the natural warmth of the soil is exhausted. It takes some weeks to cool the soil, and plants take hold at this season and start away next year as though there had been no check. Hardy Lilies should in all cases be planted in fall, but the new bulbs from Japan do not arrive until the ground is frozen up, and they have to be kept over till spring in a cool place, but where transplanting has to be done in one's own garden, the time to do it is as soon as the stalks turn yellow, as root-growth at the base of the bulbs commences with the end of the flowering season, to fortify the bulb as it were in its effort to produce a flower-shoot. This flower-stalk, when once started, is self-supporting by means of the stem-roots.

Water-lilies.

SOME specimens of *Nymphæas* sent by Mr. J. Brydon from the gardens of Miss Simpkins, of Yarmouthport, Massachusetts, are marvelous examples of the best cultivation and most vigorous growth. A flower of *N. Zanzibarensis* fully a foot across, highly colored, and on a stem about an inch in diameter, probably represents this variety in its very best form. There was also a fine specimen of the very dark purple variety, which is somewhat rare, as it seldom reproduces this rich coloring from seeds. The odor of *N. Zanzibarensis* is one of its special charms, being very distinct, deli-

cate and pleasing. Only second in size to the *N. Zanzibarensis* was a flower of the *N. gigantea*, the rare Australian species, with which few cultivators have succeeded in the open. This is a *Nymphæa* with petals less blunt than those of the *Stellata* type, and of less firm texture. The flowers are blue, shading to white toward the centre, which is crowded with a mass of thread-like golden stamens. This species is very distinct from the other tender Water-lilies, not only in its coloring and stamens, but also in its less formal character. When well established it is one of the most prolific of bloomers. The stems of these *Nymphæas* were about one foot and a half to two feet long, and as straight as canes. In a note with the flowers, Mr. Brydon says: "I claim that the finest Lilies are those grown in deep water; by deep water meaning two feet or two feet and three inches. Perhaps where it is not possible to artificially heat the pond, shallow water would be preferable, but it will be at the expense of the flowers every time. I contend that the buds of the tropicals should not show above the water more than two or three days before they open. In shallow water they are above water long before they are half-developed. I like to see them come straight up from the bottom and flower shortly after they appear above the surface. The finest flowers of *N. odorata* I ever saw were grown in four feet of water, and it seems that if this variety will do so well under such a depth of water the tropical kinds should stand much more than is commonly given them, as they are mostly strong-growing."

I have been a consistent advocate of shallow planting, but it gives me pleasure to call attention to the apparently contradictory views of so able a cultivator as Mr. Brydon, who is, no doubt, correct under the conditions given. One can scarcely cultivate plants very long before making the discovery that when growing in the open, exposed to all the contingencies of such exposure, success is at the best rather uncertain. Hence it is customary, when crops are important or especially well-grown flowers are desired, to resort to shelters or aids of some kinds. In this view, no doubt, heated tanks are very serviceable and important aids to the cultivation of *Nymphæas*. And in them, with the temperature of the water, which is such a vital matter, under control, no doubt, in an average season, the best results can be secured, and deep plantings can be made as seems necessary for the best results. But heated tanks are not always available, and my notes of my practice of shallow planting have been made in the hope of interesting the owners of small gardens in aquatics. Some of us are quite satisfied with modest results, being debarred often by expense, and sometimes by other considerations, from securing the very best results attainable. In such cases, in this latitude, with its changeable weather, not always with reliable warmth, shallow planting of *Nymphæas* is safe and satisfactory practice, as the plants are in a position to respond promptly to the quickening power of the sun.

Decay of Quince Fruit.

THERE is a destructive form of Quince decay about which the growers of Quinces are much exercised. The fruit is the object of attack, and in nearly all cases the rot begins at the blossom end. It is a dry decay and the affected portion turns a light brown, followed soon by multitudes of small pimples slightly darker than the surrounding brown. The decay penetrates to the core and ultimately involves the whole fruit.

In one orchard of a hundred trees recently visited, nearly half of the fruit, otherwise large and fine, was found with a rot-spot ranging from a mere speck at the blossom end to entire decay. It may be that some substance applied to the blossom end will assist in preserving the fruit from attack. It is possible that the tender parts of the flower may be the ones most susceptible, and by removing these when the quince is small, the enemy may be successfully resisted. Thus the calyx lobes might be removed, as they generally become brown and, lying upon the surface of the fruit, probably assist in giving the rot-fungus a foothold. It would be practicable to remove the useless parts of the blossom end of the fruit, as quinces are within easy reach of the ground, and usually only a few trees are grown. This treatment would be in addition to the spraying of Quince-trees to ward off common leaf-blight, an entirely different fungus. The enemy of the fruit is *Sphæropsis Cydoniæ*. It also preys upon the foliage and was, in fact, described from specimens from leaves. It has not, this season, been found upon the foliage of the trees.

The decaying fruit is worthless and should be picked off and burned. If left upon the trees or ground, the fungus will mature a vast number of its oval brown spores and menace the quince crop next year.

Correspondence.

Frozen Chrysanthemums at the Royal Aquarium.

To the Editor of GARDEN AND FOREST:

Sir,—On the first page of this morning's *Standard*, sandwiched between an announcement of fireworks at the Crystal Palace and another of Buffalo Bill's Wild West, the following paragraph caught my eye:

"Royal Aquarium: The National Chrysanthemum Society's Grand Show of early Chrysanthemums, Dahlias and Gladioli will be unusually interesting, showing new varieties brought from the antipodes to this country in frozen blocks of ice."

A few hours later I was paying my shilling at the entrance turnstile. The Royal Aquarium is a long brick building with a glass roof, reminding one in its architecture of a good many railway-stations. It stands in a back street, within a stone's-throw of Westminster Abbey, fortunately where it cannot mar that stately of London's groups of towers, which the Houses of Parliament and St. Margaret's join with the Abbey to compose. The last time I remember passing it, the building was liberally bespotted with huge posters announcing the presence within of Niagara with real water, and an English lady had told me that she thought it "very kind of the Americans to send the falls over." But now the vast inner hall was filled with a bewildering choice of attractions. Just within the door was a shooting-gallery; beyond, a loud-voiced phrenologist was assuring his audience that the "subject" under consideration "ad such a 'ead that 'e'd make a capital heditor." Further still, there was a small stage, its lowered curtain covered with what was perhaps an attempt to picture the mythical Snake-plant of Central America.

Rounding the empty dress-circle of this expectant theatre the flower-exhibit appeared, admirably arranged on parallel tables, set well apart, and culminating at the further end with huge pyramids of Chrysanthemum-plants and the frozen blossoms from New Zealand. Passing up to these, the chief attraction, one was detained by the superb specimens of the Madame Desgranges Chrysanthemum. The perfection of these great, soft, snowy heads is indescribable, and there was a sport of this variety, to which a medal had been awarded, where a delicate pink tip appeared on the three outer rows of petals. It rivaled the original in beauty, but no name has yet been given it. The professional decorator may be earnestly recommended to place side by side, exactly as they were to be found here, Mrs. Burrell and the Incognita, for theirs are the peculiar shades of yellow and pink which make a charming combination. There were, upon the whole, few startling novelties to note; the efforts which the gardeners have been making in the line of mauve and purple tints have not as yet been really successful. The Louis Boehmer, whose hairy pink florets were first seen in America, has sprung into favor here, and there were some splendid specimens on view, maintaining the reputation of the variety for hardy growth and free bloom. The color, too, is superb, a rich, deep, almost oriental, pink. One gardener at my elbow declared that it had darkened since its arrival in England.—[This "rich, deep color" is not the strong point of this variety, as it has been seen in America.—ED.]

All this, however, is in passing to the great attraction, which proved curious enough. The blooming-time of Chrysanthemums in New Zealand is in our spring, and last April eight flawless blooms of six distinct varieties had been cut, plunged each in a zinc cylinder filled with water and frozen solid. These cylinders were in turn packed and frozen in a zinc tank and thus shipped to London, where they had been waiting a month for this exhibition. When the various receptacles were opened and sufficiently thawed to make it possible to discern the blossoms lying imbedded in their cakes of ice they were found to be wonderfully well preserved. Save for a little discoloration at the edges, as from the nip of sudden frost, their tints were as fresh as any there—the livid pink of the Zealandi, the lemon-yellow Tarawera and the white, hairy Rimutaka. Mr. John Easland, of Wellington, New Zealand, who conceived this application of the freezing process, received from the committee a medal and certificates galore, but probably the furnishing of Covent Garden Flower Market will not become a large branch of New Zealand trade. It is the botanical lecturer or other specialist who is likely to seize on the idea and make infinite use of it. The great advantage of being able to preserve a given specimen indefinitely and produce it at an hour's notice must have occurred to every one who saw how successful was the experiment tested yesterday at the Royal Aquarium.—[Flowers in blocks of ice were seen at a New York exhibition some years ago, but they made no sensation.—ED.]

I longed to show the English florists, by the same means, what our roadside Asters were like at their best. Golden-rods they have learned to grow fairly well here, though not as perfectly as in Belgium, and one sees more of them every year, while their Firefly Lobelia (*L. flagrans*) seems at first glance the very Cardinal Flower of our brooksides, only a little enlarged and improved; but the white and mauve Asters, which they have transplanted from our New England lanes and display among their hardy flowers, make but a pitiful show.

The Dahlias exhibited were almost better than the Chrysanthemums—especially the loose, open Cactus Dahlias, which were shown in tints of astonishing depth and splendor. It seems a pity that prizes should still be offered for the huge double Dahlias and that florists should go on wasting their time in developing them, for the more they are developed the stiffer and more hideous they become.

The single Dahlia, on the other hand, is one of the most beautiful of flowers, as well as one of the most effective for decoration, especially adapted, as the German gardeners have discovered, to parks and lawns, while a bed of them at the garden's end will give light and color till the nipping frost. And for this purpose the old varieties, with their smooth tints, are better than the modern bicolored flowers, beautiful as many of these are in themselves.

London.

Louise Dodge.

[Double Dahlias and Camellias are stiff and formal, but with their rich colors and exquisite texture they still find admirers. Even among those who prefer single flowers, there are few who find them hideous.—ED.]

Cannas at Bay Ridge, New York.

To the Editor of GARDEN AND FOREST:

Sir,—For the study of plants in all their phases it is often instructive, and usually interesting, to seek them where growing in broad masses or in large quantities. As seen in this way one gains a more correct idea, in some respects, of their peculiarities, which are accented on a large scale. In this way the true nature of a variety can be more readily determined than by the observation of one or a score of plants. Curiosity as to the popular Crozy's Cannas led me a few days ago to the celebrated nursery of Mr. James Dean at Bay Ridge, Long Island. Mr. Dean early appreciated the value of these plants, and is growing them very largely. He has a full selection of varieties, but Madame Crozy and Star of '91 are grown in a very large way. Two plots of these, each containing several thousand plants, were a brilliant sight on a bright September afternoon, and their distinctive qualities were well emphasized. Madame Crozy as grown here averaged about five feet high, while in the adjoining plot of Star of '91 the plants were flowering uniformly at about three feet high. The foliage of the former was decidedly the most satisfactory, and so are the flowers, which are broader in petal, more compact and of a clearer, pleasanter tone of red, to which the tint of rich yellow on the margin contributed an added charm. The difference in coloring was very much more marked in some specimens which had been grown under glass. Here they both show a purity of color and a massiveness of petal far superior to those in the plantation. There was also in the same house a selection of yellow-flowering seedling plants of Mr. Dean's growing which show a surprising advance over any previous introductions of this color.

My main errand to Bay Ridge, however, was to inspect a large bed of seedlings from Madame Crozy, which are especially interesting just now. Mr. C. L. Allen, in the *American Agriculturist* for September, argues that Madame Crozy is a true species, introduced about 1820 as *Canna aurea vittata*, and later known as *C. limbata*. This claim seems to be founded on a colored plate in Loddiges' Botanical Cabinet, London, 1820, and an observation that "a large number of seedlings from Madame Crozy had last winter come absolutely true to the type, both as regards habit of growth of the plant and to the color and markings of the flowers."

Mr. Dean's results with seedlings from Madame Crozy do not confirm this species theory, as only a small proportion, perhaps five in a hundred, could be classed as true Madame Crozy; a smaller percentage were yellow, some almost pure-colored, others with different red markings, while the large proportion were of various shades of red, with narrower petals than the type, and of generally less value, although the broad margin of yellow on certain individuals produced a striking effect.

Mr. Dean is a leading trade-grower of Azaleas, Cytisuses, Lilies, Palms, etc., and has been especially noted for his suc-

cess in providing Easter flowers and plants of the highest class. One lot of 20,000 potted Bermuda Lilies was an indication of the quantity in which plants are grown here.

Elizabeth, N. J.

J. N. Gerard.

Recent Publications.

Something more than a year ago we published a condensed account of some experiments which Professor Bailey had made, to ascertain the effect of electric light upon plants grown in glass houses. Lettuce appeared to be greatly assisted by the light, and some ornamental plants produced earlier and brighter flowers under its influence, while some plants were affected injuriously. In these first experiments, the arc lamp hung inside of the house, and it was found that when the arc was screened by an opal globe or a pane of window glass, better results were obtained. This suggested the inquiries, (1) whether the glass roof itself would not furnish an appropriate screen, so that the light could be hung above it, and (2) if this were true, how much glass could one light profitably cover?

Without explaining the methods of screening the check plants, it is enough to say that an electric street-lamp was suspended over a greenhouse, and Bulletin 42 of the Cornell University Experiment Station contains a record of its effects upon a few common plants.

The benefit to Lettuce was quite as apparent this year as it was last, so that there can be no doubt as to the advantage of the electric light, in forcing it. Indeed, Mr. W. W. Rawson, of Arlington, near Boston, uses electric lights, which are run all night for the commercial forcing of Lettuce. Mr. Rawson estimates that he secures a gain of five days in a crop of Lettuce, by using this light, and as he grows three crops during the winter the total gain is two weeks of time. The gain from one crop is estimated as sufficient to pay the cost of running the lights all winter, and the effect of a 2,000-candle power lamp is marked at a distance of one hundred feet.

At the Cornell Station light was started on the 19th of October above some Boston Market Lettuce, four weeks old, and some seedling plants of Landreth's Forcing Lettuce, which were just beginning to show above the soil. The lamp seldom burned after eleven o'clock and often ran but an hour or two, and on moonlight nights it was not used at all. The house was exposed to sunlight during the day, in addition to this small and varying supply of electric light. A house which was lighted by the sun, but received no light at night, was used as a check. A clear glass globe surrounded the lamp, so that the light passed through two panes of glass, that is, the globe and the roof, before it reached the plants. In a single week after the light was started, the plants of Boston Market Lettuce began to excel those in the unlighted house, and when forty hours of electric light had been expended on them they were perceptibly ahead of the others. The plants directly under the light and from seven to ten feet from the arc were the earliest to show their superiority. On the first of November the lighted plants were one-fourth larger than the other, and showed a marked tendency to turn toward the light. The plants even in the farther extremity of the lighted compartment gained steadily throughout the experiment and were ready for market a week or ten days before those in the unlighted house, while in quality the Lettuce was indistinguishable from that grown under ordinary conditions.

Small plants of Landreth's Forcing Lettuce, which stood where they had been sown, behaved differently from the transplanted Lettuce. For the first week they were stunted, notwithstanding the fact that they were farther from the lamp than the Boston Market Lettuce plants which did so well from the outset. After some days of lingering, when the plants began to acquire three or four leaves, they rapidly recuperated and finally overtook their companions in the unlighted house, but they never showed the superiority which the transplanted ones exhibited. Professor Bailey does not attempt to give the reason for this behavior, although he had observed it before, and other experimenters have reported similar results. He considers it sufficient for his present purpose to say that it appears to be better to sow Lettuce under common conditions and then transplant the seedlings under the light after they are well established.

The extremity of the light compartment was forty feet away from the lamp and the roof is low, so that much of the light was reflected from it, and yet at this distance, where there was nothing but diffused light, the plants were much better than in the unlighted house. The experiment was repeated with second and third crops of Lettuce and with several varieties with similar results. On one bench Radishes had been planted

among the Lettuce and the interception of the light by the Radish-leaves had a marked effect on the Lettuce-plants which stood behind them, that is, these shaded plants were much smaller than those fully exposed to the light. When the Radishes were removed the shadows of the Radish-leaves could be traced on the Lettuce, and the same result was seen where the shadow of a rafter lay across the plants.

In the earlier experiments Radishes under the naked light were uniformly injured, and when the light was protected by an opal globe injury was still apparent, although it was decreased, that is, the tubers lost only from one to five per cent. in weight, while the weight of the leaves was increased. This year, under light which was strained through both a globe and a glass roof, there was an increase both in the tubers and in the tops. The best results were obtained from the sash directly under the light, where the tubers were more and larger and the tops were less. In no cases, however, have Radishes been sufficiently benefited to pay for the cost of the light.

Early Egyptian Beets were sown in the lighted and unlighted houses, and a month later, after 160 hours of electric light, the Beets in the lighted compartment were one-third larger than the others. Five months after sowing it was found that fifty-seven per cent. of the plants gave marketable tubers against only thirty-three per cent. of those in the dark house, and the total average weight of the plants in the light was about one-half an ounce greater than the weight of those in the dark house. The test of Beets, however, was not a decisive one, because the plants in the dark house received more bottom-heat than the others.

Last year, under the naked light, Spinach ran directly to seed, while plants in the unlighted beds made good edible leaves. In the present experiment, a month after the light had been shining an average of five hours a night, all the Spinach in the lighted house was ten to fifteen per cent. larger than in the unlighted beds, and there seemed to be no greater disposition to run to seed in the one case than in the other. This advantage was maintained throughout the experiment. The result was unexpected since in the first experiment this crop was very much injured by the light. This test seems to indicate that two panes of glass between the light and the plants have a remarkable influence.

Of Cauliflower it is sufficient to say that under the light they tended to grow taller than in ordinary conditions, but they made fewer and smaller heads.

One hundred Violets were set in beds a few days before the light was started, twelve to sixteen feet from the lamp. Fifty plants were covered every night with a black enameled cloth box, while provision was made for giving them ventilation, and fifty others received the light. In three weeks after the light was started the exposed plants began to bloom, while no buds could be found on the darkened bed. It was not until five weeks after the starting of the light that a flower appeared on the darkened plants, while the others continued to bloom. Twenty-five strong plants of the Daisy (*Bellis perennis*) were placed fifteen to twenty feet from the lamp, where the light was rather weak. Twenty-five others were placed in an unlighted house. In the first lot, flowers appeared four weeks after starting the light, and for a month or six weeks thereafter these plants bloomed more profusely. At that time the dark-house plants began to surpass the others in the number and size of their flowers and the vigor of the plants. In other words, the lighted plants bloomed earlier, and never made such a stocky growth, and soon exhausted themselves. It is possible that they might have endured longer if they had been established in beds for a longer time before the light was put upon them.

Most interesting were the observations as to the time when plants make their growth. It has been held that plants grow chiefly at night, when they use the material which they have manufactured during the hours of sunlight. It was natural, therefore, to inquire when the lighted plants grew, and whether they grew more rapidly during their fewer hours of darkness, or whether they grew when the light was burning. By careful measurement and record it was found that Lettuce-plants grew about as much under normal conditions in daylight as in darkness, and the periodicity of growth was very irregular. The leaves of the Lettuce grew more rapidly in the lighted house for the first week or so, after which their growth became greater in the dark house—that is, the leaves matured more quickly under the light. The records show that the electric light did not determine periodicity of growth; that increase under the light occurred only during the first days, and that growth in both houses took place in daylight as well as in darkness.

Professor Bailey's first bulletin concluded with these words:

"On the whole I am inclined to Siemens' view that there is a future for electro-horticulture." The final statement in the present bulletin is: "I am convinced that the electric light can be used to advantage in the forcing of some plants."

Notes.

Mr. S. C. Moon writes to the *Farm Journal* that the choicest and best of the early Pears with which he is acquainted is Beurre Giffard. The tree grows feebly while young, and does not bear early, so that the best way to get this fruit is to top-graft cions of it on some old and thrifty tree of an unprofitable kind. They will then grow rapidly and in a few years bear abundantly.

Mr. James MacPherson writes us that *Lilium Wallichium superbum* has lived out for two winters with him in Trenton, New Jersey, planted on a steep bank and protected with a little litter. The bulb was set nine inches deep and did not flower the first summer although it formed buds. It commenced to grow this year early in May and produced two splendid flowers about the first of August. They were much larger than any of the longiflorum type, an old-gold color inside with dark brown anthers and a texture so durable that the flowers kept perfectly for ten days.

In a review of the Rose exhibitions of the year in England a correspondent of the London *Garden* says that the most successful exhibition Roses were old and well-tried favorites, the best among the hybrid perpetuals being A. K. Williams, Charles Le Febvre, Victor Hugo, Marie Baumann, Mrs. John Laing, Gustav Piganeau, Horace Vernet and Her Majesty. In the Tea class, Edith Gifford, Madame Cuisin, Innocente Pirola, Souvenir d'Elise, Comtesse Madaillac, Francisca Cruger, Maréchal Niel, Madame Hoste, Climbing Niphotos, Madame De Watteville, Ernest Metz, the Bride, Marie Van Houtte and Cleopatra.

Many of the Hickories of northern New Jersey are losing their leaves early on account of the attack of a fungus, *Phyllosticta caryigena*. In many cases trees were observed whose foliage was quite brown by the middle of September, while neighboring trees looked fresh and green. In one group of three Hickories, on one of which the foliage seemed quite dead, the trees on either side of it, and so close to it that their branches touched, seemed entirely intact. The explanation of this can only be that some individual Hickories are more susceptible to the attack of this fungus than others, and this is true of many other plants and many other fungi.

The October number of *Meehans' Monthly* contains a good picture of the Queen of the Prairie, *Spiræa lobata*, and in his account of the plant the editor calls attention to the fact that this plant affords a good illustration of the remarkable relationship between the Atlantic flora of North America and the flora of eastern Asia, a relationship to which the attention of men of science was specially called by Professor Gray. In many cases precisely the same species are found in both places, while in other cases the species, though differing, are so closely related that their differences are scarcely to be noted. *Spiræa palmata*, of Japan, so nearly resembles this Queen of the Prairie that a casual observer would pronounce them the same species, although a critical examination shows good botanical distinctions.

According to the *Kew Bulletin*, a tea made from a species of Orchid has been drunk for some fifty years in France, and, although it is an expensive luxury, finds an ever-increasing sale. It is prepared from *Angræcum fragrans*, a species allied to the Vanilla-plant, which has a strong aromatic odor. The leaves and stalks are simply dried, without any application of heat; and, to make the tea, a small quantity of them is placed in a closed vessel filled with cold water, and boiled for ten minutes. As with ordinary tea, milk, sugar or rum may be added to this decoction or not, according to taste, and it is said to be equally agreeable whether drunk cold or hot. Material sufficient to furnish fifty cups costs about fifty cents, and its name in Paris, as in Mauritius, whence the custom of using it is said to have come, is "Faham."

We have received from Mr. Curtis A. Perry, of Braintree, Massachusetts, specimens of what seems to be a double-flowered Morning Glory (*Ipomœa purpurea*). The leaves are heart-shaped and almost as those of *Aristolochia Siphon*. The flowers are very much doubled, of a blush white color streaked with a purplish blue. Mr. Perry writes that the

plant is now profusely covered with these flowers, which stand out well beyond the leaves and make a charming sight. The seeds were brought from Mexico three years ago, and seeds from the plant then grown have produced plants each year since, in which the flowers are true to their double character. Each year the plant has begun to bloom out-of-doors in September, but it flourished well as a pot-plant last winter in an ordinary furnace-heated house. Altogether it is a most interesting plant and promises to be a valuable one.

We have received the first number of *Gardening*, a semi-monthly paper published in Chicago, which, according to its announcement, is "gotten up with the view of aiding every one who is interested in a garden." The editor is Mr. William Falconer, who is widely known as a well-equipped writer on horticultural subjects, and who has been for many years head-gardener at Dosoris, Mr. Dana's beautiful country-place on Long Island, which has been more than once described in these columns. Notes from the ornamental and useful plantations of Dosoris will be a prominent feature of the new paper. Mrs. Royle, better known by her maiden name of Emily Louise Taplin, who is also an experienced writer, is a member of the editorial staff and will be permanently located at the Chicago office. The paper resembles the *American Florist* in size and appearance, and the first number contains eleven pages of well-prepared reading-matter.

A correspondent inquires whether the bulbs of Hyacinths which have bloomed in the house in winter can be used another season. The answer depends on how the flowers are grown. If they have been flowered in water the bulbs will be useless for the future. If, however, a bulb is planted in good potting soil, and the spike is cut off after the flowers have faded, the plant, if kept properly watered, will continue to live, and the roots and leaves will store up enough plant-food in the bulb for use another year. By the way, Hyacinth-bulbs and other Dutch bulbs which are needed for early flowering should be planted at once and put in a dark place, or left out-of-doors and covered up with soil or leaves until the roots have started. They should not be brought to the light for five or six weeks, and it will not hurt them to be frozen a little. In planting leave the neck of the bulb uncovered and have the earth firmly pressed about it.

The *Gardeners' Chronicle* for September 17th quotes at length, and with elaborate comment, Bulletin No. 41 of the Cornell Experiment Station on the "Comparative Merits of Steam and Hot-water Heating for Greenhouses," at the close of which we find the following editorial comment: "Incidentally, we may note the fact that the report which has formed the subject of our comment is itself founded upon a thesis prepared for a Bachelor's Degree by Mr. F. W. Card, at present a Fellow in Horticulture. Imagine a student of Oxford, Cambridge, and even London, writing a thesis on steam boilers for a Degree of Horticulture! Our American friends are a long way ahead of us in these matters, and while we gardeners are moaning over a low rate of wages, the overabundant supply of gardeners and inadequate social status, the Americans are extending the bounds of horticultural science, supplying a more thorough education, recognizing talent by means of university degrees, and thus, while raising the whole standard of efficiency, they are lifting the gardener to the position he ought to occupy."

About ten years ago, some three acres of land in this city, along the East River between Eighty-fourth and Eighty-sixth Streets, which had been a sort of beer-garden or picnic-grounds, were taken by the city and called East River Park. Under the Small Parks Act last winter, seven acres were added to this, which extended the water-front of the park to Ninetieth Street. Behind the park is a very dense population, and before it is deep water, which rushes through a narrow channel and always brings with it a cool breeze. The portion just added, and which is connected with the lower part by two bridges which span Eighty-sixth Street, was once an old homestead, and the house, a century old with broad piazzas, is left standing. There are some good trees on the grounds, among them an immense Button-ball, probably the largest on Manhattan Island. The plans for the improvement of this park have been adopted, and the Department is actively at work in making it ready, and it will be completed probably next year. No carriage-roads are provided, but there are playgrounds and grass and shade, and from the high bluff above the river the views to the north and east over the water are superb. Altogether it is a wonderfully attractive spot, and for its size it will be one of the most useful pleasure-grounds in the city.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

Gardening a Human Bond.

IF there is one pursuit that forms a link between human beings of different stations and habits, gardening is certainly that occupation, for whether it be the vocation or the avocation of man or woman, it appeals to so fundamental a taste that it makes a common ground upon which all can meet with interest and sympathy. It is the primal occupation of man; the final result and joy of his highest civilization. From the clod we come, to the clod we return, actually and figuratively, our fashioning from the dust of the earth pointing plainly to the fact that man was a graminivorous creation, deriving his sustenance from the grains he rescued from the tropic sands where he originated. It is a theory of the historical philosophers that man first developed into civilization in some rainless and unchanging region like Egypt, or the western slope of the Andes, and that there, under unvarying conditions of climate, he first established communities, and tilled the soil—hence, possibly, this old idea of his evolution from the dust of the earth.

As the animal with forethought to plant and dig was an advance upon his predecessors, so the agriculturist is a higher development than the nomad who goes in pursuit of his crops instead of waiting for them to come to him; and it is a curious fact that after man has circled the globe in pursuit of wealth or amusement, he comes back to the culture of his own acres as the most dignified and satisfactory ending of his career, the only one which is not an anti-climax. Contented and not inglorious, Cincinnatus returns to his plow, Washington to Mount Vernon, Jefferson to Monticello, and Mr. Gladstone to Harwarden. The spectacle of Mr. Pitt, happy in a three-years release from political life, and enthusiastic in the culture of his garden, is one unfamiliar to the world, which scarcely disconnects him from the great area in which he was the central figure, but is gratifying as an evidence of the humanness of that

great statesman, and of that solid wisdom of which he gave perpetual proof in his public career.

Poets and philosophers alike have rejoiced in rural shades, in the charm of pleasant labor among their flowers and trees. Gardening is the delight of royalty and the comfort of the cottager. The greatest ladies in England have taken pride in designing their own parterres, while the game-keeper's daughter rejoices in her little square of flowers. It is an occupation for the very rich, a solace for the very poor. It can occupy acres of territory, it can be carried on within the limits of a grocery-box. It is the priceless heritage of man, this right to till the soil, this joy in its accomplishment. Whether the results be utilitarian or æsthetic, the satisfaction is common to all, there is no monopoly of this privilege. In this great half-occupied country of ours, it is easily possible for a man to possess a morsel of territory for his own cabbage or marigold. There comes a period in the lives of most when this primal desire demands accomplishment. Then upon his fragment of the earth's surface a man sits down, and content begins. Not idle content, certainly, since only by the sweat of his brow can man overcome nature, but that discounted content which is the human substitute for happiness.

Results may disappoint in detail, but the aggregate produces a certain mental well-being which peer and peasant alike share. The triumph of the harvest is for all, and though there may be years when harvests fail, they are the exception. There may be a harvest of the spirit, even if the crops fall short, a gain in health and knowledge from the hours of labor that are a balancing gain for disappointment. It is not only material results we gather in, but the harvest of experience, the gain of wisdom, the science for the coming years, and in these human benefits there are no hampering trusts. The planter may sell his crops a year or two ahead, and find himself short of the market, but there is no corner in experience which confines it to a chosen few, and of this gain the gardener, be he high or low, may be sure, so that his labor can never be a dead loss.

Moreover, he who loves his garden is in touch with his kind, whether he find himself in Columbia or Cathay, for on this topic all may meet, the Russian mujik and the Czar, the Egyptian fellah and the Bey, the American traveler and the Daimio of Japan. There are gardens from Babylon to the Golden Gate which have delighted the heart of man from Eden until this day. To be cast out from a garden was the curse of Adam, and the struggle of fallen man ever since has been to repair that primal disaster. A hankering for an Eden is at the bottom of our wandering souls, and we are ever striving to fashion it to our conception of the lost Paradise. The idea is common to all—the expression varies in each individual. If originality inspires the owner, the garden will be original; if the conventionalities be dear to him, you will find formality in the arrangement of his flower-beds; the artist will interweave it with his taste and fancy; the poet will seek in it to embody his dream; the practical man will turn it into a Potato-field; the speculator will plant it with Wheat; a sentimentalist will fill it with Roses and Lilies; an æsthetic, with Sunflowers. And from whatever clime you come you will read the man in his garden, nor need an interpreter to explain him to you.

There is no region where man's effort to reclaim the soil does not possess an interest for all other men. No tale of the march of conquering hordes captivates like the story of the founding of a state, and the state's foundations are laid by its plowshares. In Egypt the great river has been harnessed for the service of man; in Holland he has fought the sea to win a foothold for his sturdy independence, a garden for his bulbs. With the Romans marched the culture of Europe; in the wake of their great armies sprang up the cereals and the trees of the forest. Cæsar was no less a conqueror of the soil than of opposing armies. He carried in one hand the sword, in the other the life-giving grain. To him, first of all, Britain owes the planting of her

barren acres with fruit-trees, with the Lime, the Chestnut and the Plane; possibly with the Elm itself, though Dr. Walker thinks that noble tree may have been brought there by a Crusader. And strange fact in the history of man, his triumph is the triumph also of the garden—its seeds and nuts, its grains and flowers springing up in the footsteps of Alexander and Xerxes, of Crusader and Spanish Don, to flourish and comfort long after the mailed hand that brought them was dust.

Thus in the path of the oppressor came a blessing, "out of the strong came forth sweetness." Here again that human touch links us with the old warrior of the past, bringing home from Damascus a Rose-slip to gladden the garden of his sweetheart, a sprig of vine to commemorate the hills of Palestine on the borders of some English lake. It is pleasant to think how the memory of his own garden made the Macedonian bring home to Greece the flowers that his master wrested from Darius. The Rose from Persia, the Lily of the farther East, are a bond of common interest between the old world and the new; between the mailed Past and prosperous Present. The Lotus of the Pharaohs is the glory of a Jersey mill-pond, the Pæony of the Hoang Ho is the ornament of a dooryard by the Charles, our very weeds bind us together to fight a common enemy, and thus the love and care of a garden brings man into fellowship with all the sons of Adam.

It was recently argued in these columns that it would be desirable for women of artistic taste to learn how to employ it in the proper planning and embellishment of the grounds of their homes, as well as the interiors of their dwellings. If women develop capacity in this direction there should be opportunity for their employment in a professional way. Some prejudices as to what constitutes a proper occupation for women would need first to be removed. We have in mind the case of a young woman whose father was superintendent of the park system, in a flourishing New England city, and who developed such a taste and capacity for the work that she became his most capable assistant. The eminent landscape-architect who had designed the parks of the place recommended, on the death of the superintendent, that his daughter be made his successor. She knew the duties of the position thoroughly and appeared altogether the most fit and competent person available for the position. The park commissioners promised to appoint her but failed to keep their word, giving as a reason that, while they really desired to do so, the local politicians would never sanction the appointment of a woman to an important position like that. Architecture is becoming a pursuit for women, and our leading architectural journal welcomes them to the profession, saying that their knowledge of household requirements makes them peculiarly valuable in the planning and designing of dwellings. There is no reason why women should not enter callings that bring them into the healthy life of the open air, if no hard manual labor is demanded. Therefore landscape-gardening is a suitable employment for those who are capable in this direction. Women are now giving themselves to horticulture and floriculture to a considerable extent; in the latter, particularly, their almost universal love of flowers gives them a peculiar fitness for such work. Schools for the training of girls in these employments would be admirable institutions.

In this connection a novel occupation for women, that has just been brought to our attention, is worthy of mention. The park commissioners of Lynn have recently established a carriage service in their noble great pleasure-ground, the Lynn Woods. At present but one carriage is run, and it is driven by the wife of the man to whom the contract was given, she being fond of open-air life. The fact is highly appreciated by the women who, with their children, form the great majority of the patrons, for their driver has a very pleasant and friendly way of pointing out the interesting features of the beautiful route. Why should not a woman,

who understands thoroughly how to handle horses, make an occupation of taking women and children on drives through interesting and pleasant places?

ALL persons who are interested in the preservation of our forests will be pleased to see any efforts to secure economical methods in the manufacture of lumber. Of course, there is a large amount of material which goes to waste, in the shape of slabs, edgings, etc. From twelve and a half to twenty-five and a half per cent. of every log is turned into sawdust, and in addition to the other waste not more than fifty or seventy-five per cent. of any log is used. A great many mills make laths and pickets and the like from slabs, but, after all, the amount of waste which is burned is enormous. In an article entitled the "Waste from Pine Forests," the *Northwestern Lumberman* comments on the large amount of good material that is wasted in such an instructive way that we give in a condensed form a portion of the article:

The examination of any slab pile will show that much of it can be converted into small articles of common use, which only require lumber which is too short to be used for lath, pickets or similar stock. Staves for pails and tubs, material for cutlery trays, a vast variety of small boxes, material for toys in endless variety, handles of domestic utensils, window-sash, blinds and screens, besides bridging and small stuff in house-building, can all be manufactured out of these waste products. Perhaps it is safe to say that all these articles, which are used within the limits of the north-west Pine states, could be made from the waste of the saw-mills which at present is destroyed at great expense, and is only a source of annoyance. This is especially true also of the Yellow Pine districts in the Pacific states. Only a small proportion of the articles named are manufactured in Washington, Oregon and California, that is, while these states are spending money to get rid of the waste of their saw-mills they are importing articles which could be made from this same waste. In any given quantity of logs in California, hardly forty per cent. of their cubical contents ever reaches the market in the shape of merchantable lumber, as can be seen by any one who examines the saw-mills among the red-wood or pine of the Cascade range or the Sierra Nevada foot-hills. The wastage in the Yellow Pine country runs from thirty-seven and a half per cent. to fifty per cent. of the cubical contents of the log, or, in other words, on an average not over fifty-eight per cent. of the log reaches the market. In England and Continental Europe and in the older states of the east almost every saw-mill has in connection with it some shop for working the refuse from the mill proper into merchantable articles, and in many cases the saw-mill is an adjunct of the other department instead of the reverse, so that the loss of the material of the log is reduced to a minimum in Europe. This working up of forest-products does not stop with the saw-mill waste, but takes up the waste in the forest itself during the process of logging.

In Massachusetts, Vermont and Connecticut, the great number of little mills have no necessity for a fire-pit, and the choicest pieces of waste can be carried away in a basket. Nowhere in Europe, except in the Scandinavian peninsula and in the Baltic provinces, is timber cut primarily for the sake of what is ordinarily called lumber. In most countries there are government regulations to prevent the loss of forest-material by manufacturers. Such an interference would be resented in this country, but it must come in time. If a man with a million dollars in paper currency should be found burning it up, the state would interfere to prevent his insane waste in the interest of his heirs and in order to prevent him from becoming a public charge, and the time is rapidly coming when the question of saving the waste of forest-products, together with saving the energy lost in the combustion of costly fuels, will demand the attention of the best brains of the country, if not governmental interference.

Certainly these are the most brilliant days in the year, especially when ushered in by a frosty morning which bears the same relation to a merely dry or foggy one at this season that a dewy morning bears to a parched and languid one in summer. The year seems ripened like a fruit by frost, and puts on the splendid tints of maturity but not yet the color of decay. It is not sere and withered as in November.—*Thoreau's Journal*, Oct. 10th, 1857.

A Florida Live Oak.

A SHORT distance to the westward of the Ponce de Leon Hotel, at St. Augustine, grows a Live Oak (*Quercus Virginiana*), which even the most impassive guest notices and admires as he drives by. The extremities of its lateral limbs, after the manner of the Live Oak when growing alone, almost sweep the earth's surface, and its branches form a singularly perfect hemisphere, as may be seen in the illustrations on pages 486 and 487, made from photographs taken in early March of the current year. A measuring line of fifty feet, drawn from the middle point of the first fork and through this hemisphere, will reach its exterior limits with remarkable uniformity at the tips of all the great limbs. The tree is on the ground of Mrs. Hanna, and the neighbors make the improbable statement that it was planted about a hundred years ago. Eighteen inches above the ground it is fourteen feet one inch in circumference, and the principal limb has a girth of six feet. This tree is doubtless the largest in its vicinity, but in the rich bottom-land of the St. John, near Jacksonville, I have seen specimens of the same species which I believe to be larger, and I have had described to me one on the Ashley River, near Drayton Manor, with a spread of branches one hundred and twenty-eight feet in diameter.

Enormous must be the torsional strains thrown upon the sturdy trunk of the St. Augustine Oak when the winds that sweep up from the sea twist and wrench the great whorl of tough limbs that seem a wheel of levers formed to tear the tree from its hold upon the earth. And the hurricanes have left a record of long and labored resistance, in the sinewy form of the bole, where swelling cords of fibre bind together limbs and roots, and the fine modeling of the wood suggests the welter arm of a wrestler whose muscles have been trained and shaped in the life and death struggles of the arena. This grand trunk is coated with a soft gray bark upon which the sunlight, reflected from the shining sand, falls with wonderful effect, illuminating a network of crisp ridges and channels, all finely wrought, incised, fretted and frosted as though cut and chased with the chisel and graver of some inspired artist from a mass of virgin silver ore.

New York.

Robert H. Lamborn.

Shongum.—III.

A MAN once made himself famous by bringing to notice the Providential nature of the fact that great rivers always ran near large cities. In humble imitation, let me suggest the beneficent intent with which a mountain-range of easy access, and so full of elements of health and pleasure, was placed so near the large centres of population on the Atlantic coast.

It is almost to be regretted, that the state cannot keep the right of eminent domain over these cliffs and lakes and forests, that may in time rival the primeval ones in grandeur. Wise forestry laws, and the planting of trees to produce the best quality of timber in places now denuded, or where the growth is worthless, would greatly increase the resources of the state and furnish employment and homes for many of its now idle citizens. Forests growing on the uplands would fill the diminished water-springs and fertilize the wide valleys of the Walkill and the Roundout. Fine-grained sandstone, which takes a polish like marble, is found here in unlimited quantities, and is well adapted for all architectural purposes. There is space enough in these vast solitudes for innumerable stately homes with wide lawns and sunny gardens, without encroaching upon the restful and health-giving recesses of the forest. The fine shale which underlies the sandstone and comes to the surface in various places could be used to make, through all the length of the range, roads as good for driving as those which now add so greatly to the attractions of Mohonk. Under the paternal government of Bellamy's dream, the region would support a large population in peace and plenty, and still afford breathing-space for the dwellers of the city in their hours of leisure.

From Millbank Mountain, which is nearly the highest point of the outside wall so abruptly separating this region from the valley, we came by an easy carriage-road to the edge of the cliff. Here we climbed a few steps upward over a glacier-polished dome, and looked down 1,300 feet to the farms below. Standing upon the bastion of the rock that projects a little below the highest ledge, we dropped a stone, and by timing its fall measured the depth of the abrupt descent. Seven hundred feet below it struck the flat top of the foundation-wall, and then bounded into the vale beneath. The strength of fibre in a Yellow Pine growing in this exposed situation

compelled admiration. Though it had been from infancy buffeted by the tempest, it had grown strong and straight, fully thirty feet high, with a well-developed crown of foliage. Its fellows were less vigorous, many even bent and broken, and some, like alpine trees, deliberately lay down to grow.

Millbrook and High Point, rising above the other peaks, look at each other evenly across a distance of a few miles. Sewockenomo and Onaghtin, chiefs of the Esopus tribe, must often have looked anxiously from these points over to the Hudson River, where colonies of the Dutch had been established. On May 16, 1664, they signed the treaty by which the whites took peaceable possession of the land. These historic names might well take the place of the common names the peaks now bear. Palmaghatt, which sounds oriental but is probably an Indian relic, is the name of a deep, narrow ravine, opening between two sections of these upright walls and ending in the upper valley beneath one side of High Point. It is two miles long, and in some places not more than thirty feet wide, with an average width of fifty feet. For most of the length these walls are from ninety to two hundred feet high, but as they widen reach a greater elevation. A small brook, fed by springs or by subterranean leakage from the lake, runs through Palmaghatt, but is so covered by broken trees and fallen rocks that though its musical tinklings are often heard three feet beneath the elastic surface, its waters seldom come to light. This deep, damp soil once nourished gigantic Hemlocks, long since felled and stripped of their bark. Their successors, which we trust the woodman of the future will spare, bid fair to equal them. Here the Yellow Birch also grows very large and tall, and to one looking down from above the ravine seems full of leafage like a bit of the primeval forest and must have afforded a safe hiding-place in the Indian wars.

Mossy Glen is a larger basin and similar to that through which the Awasting flows, but wider and more open to the sun. Its bordering walls hint at seismic disturbance, or the level strata seem to have loosened and twisted on their foundations, and at one point the great square rocks have fallen and are heaped together like the ruins of a temple. Here, too, the soil is deep. The smaller growth has been judiciously cut and the larger trees have space for full development. We measured a Black Birch seven feet four inches around, four feet above its roots, and a White Birch eight feet two inches, and there were many trees as large as these. There were many Hemlocks as large as those in Palmaghatt, and though most of the oldest trees had long ago been removed, their decaying stumps told the story of former grandeur. One recently cut lay on the ground entire and stripped of its bark; the butt measured forty-nine inches in diameter. The Birch-trees were unusually tall and straight, lifting their leafy canopies twenty feet above us.

These trees are also interesting from their power of adapting themselves to circumstances. I came upon one which grew with quiet grace beside a rock, but on one side had thrown out a buttress that divided itself into branches four inches in thickness and then run into the ground. On closer inspection I found that the supposed rock was the large root of an older tree decayed past all shape, while the stem lay behind it a mere bank of Mosses. Then I knew what had happened. The young Birch had begun to grow at the root of an older tree. Some other applicant for the same position had crowded it and curved its stem. The old tree fell one day and the Birch found itself with its face to the ground, its deformed back making a curve in the air. In the upheaval the crowding neighbor had disappeared, and the two lower branches that had before drooped near its roots were looking up to the sky. What messages were sent from head to foot, what answers were whispered by the trembling leaves, we shall never know, but these two branches have grown into tall trees of equal height, the parent stem and other branches having willingly buried themselves to sustain the symmetry of the favored pair. If these dumb children of earth could speak, what stories they might tell of fortune and misfortune, of fear and desire. To one who observes closely, there is so much individuality in native growth. It appeals to the imagination as nothing cultivated can do.

At the eastern end of Lake Minnewaska stand a Birch and a Hemlock, their twisted roots giving evidence of some dramatic incident in their early history. The water here is shallow and the border level for a space, and other trees grow straight and commonplace. But these in seedhood, perhaps, perceived some need of mutual help, or else struggled together over some plant-food until their roots became strangely interlocked, looped back and forth and twisted together like the limbs of athletes wrestling. But now Tsuga, without ap-

parent reason, leans out over the lake, and *Betula* holds him so firmly he cannot fall. I looked and wondered what history was thus told, until I thought I heard the *Hamadryads* laugh. The sound seemed to come from a distance, but that was, no doubt, a trick of the sly creatures. I have before spoken of the mixed growth of trees here, and the sudden transitions of level within a small area gives place for an equal diversity of flowers. Within four miles around the lake I have noticed seventy varieties of blossoming and fruit-bearing plants. The *Asters* and *Asteroidæ* are now in great wealth of bloom, and some varieties of special beauty. *Coreopsis* and many kinds of *Solidago* make the rocks and road-sides gay. Beside the *Peterkill* fall the *Chelone* contrasts its spikes of rose and purple with the white umbels of *Eupatorium*. *Heliopsis* and *Helianthus* show two variations, and there is a very fine *H. tuberosa* that I think has strayed from some garden. There are three kinds of *Trillium*. The *Montropa uniflora* is unusually large and beautiful in shady places, and I have found also the *Medeola Virginica* holding its purple berry in its crimson-tinted involucre instead of the white petals that drooped there when I saw it in April in the mountains of North Carolina. There is a rare and beautiful low-growing evergreen, *Corema Conradii*, to be found in *Palmaghatt*, and an aromatic Fern new to me, *Aspidium fragrans*.

The adaptation of soil and climate here to the growth of flowers is proved not only by the abundance of wild bloom, but by the rich beauty of the gardens at Mohonk. It has been said that we think we can improve upon nature by shaving a lawn and making impertinent flower-beds. But the skill with which groups of flowers have been massed in harmonizing or contrasting colors around the pretty pavilions and arranged to give effect to the wide sweep of the lawn, delights the eyes that may be a little weary with the monotony of woodland tints. On the higher levels of these mountains the prevailing growth is of Yellow Pine (*Pinus mitis*), but the Pitch Pine (*P. rigida*) is frequent, and here and there is seen a remnant of an older forest, *P. strobus*, standing high above the younger generation. Sometimes there is only a naked giant, scathed by lightning or killed by more ignoble fires, but often wearing a crown of sombre glory, and as vigorous as in youth. These trees, whose needles do not retain moisture as do the deciduous trees, increase the dryness of the pure sunlit atmosphere and give it the spicy and resinous fragrance so welcome to the invalid.

Minnewaska, N. Y.

M. H. P.

Oil-making in Italy.

THE Italian autumn gains a fresh picturesqueness from the active groups about the Olive-trees engaged in the harvest of this classic fruit, which is still treated with old-world conservatism, after the antique methods of the forefathers. On the ground are spread great sheets, upon which the fruit is heaped as it is gathered, and busy groups come and go around, even the old gray-foliaged twisted trees, whose tormented attitudes suggest always that they are at variance with the climate, and are fretting after a warmer region sheltered from Mediterranean winds and the cold breath of the *tramontana*.

The Olive-picking is a delicate business, for it is useless to gather the crop before it is ripe enough, and no less disastrous to delay a day too long, so in the heaps of gathered fruit quite a third of the berries are usually green. Like the high-bush Blackberry of our native land, the fruit turns from green through red to a bluish black. It needs gentle handling, and ought always to be picked by hand. Nor is this a difficult matter, for the trees, if properly cultivated, are well cut back to keep them stocky, while the branches are cleared out from the centre and trimmed across the top, at about fifteen feet from the ground, as smoothly as any hedge-row in England. Once brought to the desired shape and size, they can be so maintained for centuries. The flavor of the fruit is said to improve with the age of the tree. The Olive-trees on the slopes below *Tivoli* are said to have seen the Emperor *Hadrian's* sumptuous villa in all its splendor.

The men use ladders and take charge of the upper branches; the women, bare-headed or brightly kerchiefed, stand about and pick all the fruit within reach; children swarm about the ground for the fallen berries. They sing a snatch of some Tuscan stornello, which is taken up and carried on from tree to tree and orchard to orchard; but in the midst of the strain they break off to indulge in a bout of the most unsparing chaff, to dispute some mandate of the overseer, or to pay their respects to the *padrone* or owner of the property as he passes, mounted on his sure-footed little pony. Over all the sun is shining gloriously, in a sky so blue that the gray Olive-leaves

turn white against it, and so still as to seem almost unearthly to one accustomed to the atmospheric unrest of New England.

When their large, flat baskets are full the pickers take them to the granaries to be emptied. The sooner the berry can pass from the tree to the mill the better, says the Tuscan farmer, but though the machines are kept working night and day in the height of the season, they do not suffice if the crop be large, and the superfluous berries are carefully spread in thin layers upon dry floors. There is in the olive a thin watery liquid, the same which makes the fresh fruit at once so nauseating and bitter to the taste, and this, almost as soon as the olive has left the tree, begins to ferment and work its way out of the fruit. It must dry off at once or a mold forms upon the berries, which renders them absolutely worthless.

As soon as may be, therefore, the olives are picked over, cleared of leaves, washed, if necessary, and taken to the press. Since oil-making demands, above all things, an equable temperature during all its processes, the *oliviera*, as it is called hereabout, is usually installed under ground. Accepting an invitation to enter one of these the other day, we found ourselves, when once our eyes were used to the dim light, in a great branching cavern, hollowed out of the soft rock of the Sienese hill-side. Above was a roughly groined ceiling, on our right the olive-presses proper, before us the machines for crushing the fruit, and beyond a charcoal fire with a huge kettle of boiling water suspended above it. In a dark corner a door led to the inner cave, where the oil is clarified.

There were two crushing machines at work when we entered. The base of each consisted of a huge circular block of the yellow marble of Siena, seven feet in diameter, eighteen inches high upon the outer edge, and sloping inward to a depth of about six inches in the centre. Here was inserted a massive iron pivot, with a short arm attached to a mill-stone of the same beautiful stone as the base, and which was driven round and round in the cavity by one of those sturdy little ponies which are the pet and pride of every Tuscan farmer. Unwearyingly these two closely clipped, mouse-colored, willing beasts kept at their monotonous task, giving a friendly nip at one another as they met on their circling paths or responding to a caressing word by a hasty rub of the head on the shoulder or arm of the driver, but never lagging for an instant on their unending round.

Into the hollow of the lower stone is first thrown a heap of Olives, perhaps two or three pecks, a little boiling water is added and the horse starts off. The water has to be renewed from time to time, and the revolving stone, which has been so set as to detach the pulp as much as may be without breaking the stone of the fruit, not only bruises the berry but slowly forces the whole mass of pulp about the cavity. After some fifty minutes it will have made a complete revolution and it is then ready for the first pressing, which yields the finest oil. After this the pulp goes back to the mill-stones for a further crushing, is then repressed for second-class oil and the refuse of this is sold to the proprietor of a steam-press, who still succeeds in extracting a profitable amount of machine-oil.

Steam in new establishments often replaces horse-power at the crushing-mill, but the press is always worked by hand. It takes intelligence—and experience too—to tell when the screw has received a sufficient number of turns and when the pressure may again be increased. The crushed olives, called at this stage *lansa*, are confined under the screw-press by means of gabbie, which look, as you see them hanging before the shop-door, like elaborately twisted coils of clothes-line, but which are really bags woven in circular shape, each capable of holding two or three quarts of pulp. A half-dozen of these are slipped over the upright of the iron screw-press, which has long replaced the clumsy wooden lever of early Roman days, and pressure is put on most gently and cautiously for the first quality of oil, but with less precaution for the second grade when the stones have been crushed.

The oil, as it runs from the press to the great earthen jar beneath, appears of a brownish color, owing to the presence of the bitter watery liquid before mentioned. The specific gravity of this and of the oil proper is, however, so different that the work of clarifying begins at once and spontaneously. It is assisted and consummated in the dim inner dungeon, but the secret of this process is never revealed. The great vases of rude pottery are ranged about the walls, each displaying a more advanced stage in the clarification of its contents, till finally a beautiful smooth, translucent, greenish yellow liquid is revealed. But it is not wholly out of politeness, as we know, that the three workmen suspend their labors when we come in, and though their chief makes the round of the little room with the greatest affability and responds with true Italian courtesy to every question, his elaborate answers are distinctly vague.

"Water is used, in a proper quantity, at a proper temperature, which he himself determines; the oil is poured back and forth a proper number of times, when that seems the proper thing to do. The Signorine must find all these details very dry, and he asks their pardon for troubling them." The Signorine know at all events when questions are useless, and with an exchange of compliments take their leave.

When the oil comes out of the magician's black cave, it is ready for the market, but it is usually kept on hand for a time in a store-room, the floor of which slopes toward a central hole, under which a great earthen jar is set. If no breakage occurs, the only further care the oil receives is to be trans-vased as a precaution against fermentation when the great summer heats begin in June; otherwise it simply stands and waits its market. About thirty-five per cent. duty, ad valorem, is paid on it when it enters the city gates, and the shop-keeper doubtless takes his profit, but even so, the finest quality costs the house-keeper twenty-seven or twenty-eight cents a quart, and the finest quality is used, not only for the table and in cooking, where it admirably replaces lard and butter for frying and basting—but even in the tall classic lamps. "Anything but the very best always has an evil odor," the servants say, and they are doubtless right, but it always pains my New England thrift to see the beautiful greenish golden liquid put to so base a use.

Sienna, Italy.

New or Little-known Plants.

New Orchids.

PLEUROTHALLIS SUBULATA, Rolfe.—A species allied to *P. cardiostallis*, Rchb. f., with cordate-oblong leaves and dark lurid purple flowers, from the collection of Baron Henby, of Peckau, Bohemia. Its native country has not been recorded.—*Kew Bulletin*, p. 137.

RESTREPIA ECUADORENSIS, Rolfe.—An Ecuadorean species allied to *R. antennifera*, Kunth, but with shorter lateral sepals and other differences, though with a general resemblance in coloration. It was imported by Messrs. F. Sander & Co., of St. Albans, and flowered in their collection.—*Kew Bulletin*, p. 138.

RESTREPIA SHUTTLEWORTHII, Rolfe.—A small brightly colored species, imported by Messrs. Charlesworth, Shuttleworth & Co., of Heaton, Bradford, and flowered both in their collection and at Kew. It is allied to the Guatemalan *R. xanthophthalma*, Rchb. f., but, besides other differences, the flowers are more heavily marked with crimson-purple blotches.—*Kew Bulletin*, p. 138.

DENDROBIUM PLATYCAULON, Rolfe.—A very singular species, introduced from the Philippine Islands by Messrs. F. Sander & Co., of St. Albans, with whom it flowered. It is allied to *D. lamellatum*, Lindl., but the flowers are twice as large and the lip quite different. The pseudo-bulbs are curiously flattened, and bear three to five leaves near the apex, and racemes of three to six straw-colored flowers.—*Kew Bulletin*, p. 139.

BULBOPHYLLUM DENSIFLORUM, Rolfe.—A small species allied to *B. triste*, Rchb. f., but with a long raceme of yellow instead of deep purple flowers. It is a native of the eastern Himalayas, and was sent to Kew for determination by Mr. N. Campy, The Gardens, Thedden Grange, Alton, Hants.—*Kew Bulletin*, p. 139.

ERIA CRISTATA, Rolfe.—A pretty little species, allied to *E. marginata*, Rolfe, and, like all other species of the section *Cylindrolobus*, having large petaloid bracts. The flowers are white, with some yellow markings on the lip and a hairy crest at the base of the front lobe of the same. It is a native of Moulmein, and was sent to Kew by Mr. C. Peché.—*Kew Bulletin*, p. 139.

ODONTOGLOSSUM AURICULATUM, Rolfe.—A pretty little species allied to *O. Lindleyanum*, Rchb. f., but differing in its hastately-trilobed lip, whose disk is light purple instead of brown. It was imported by Messrs. F. Sander & Co., of St. Albans, together with *O. Nœvium*, Lindl. The name is given in reference to the ear-like side lobes of the lip.—*Kew Bulletin*, p. 140.

ODONTOGLOSSUM GUTTATUM, Rolfe.—An interesting species allied to *O. odoratum*, Lindl., and *O. præstans*, Rchb. f.,

with light yellow flowers irregularly blotched with chocolate. It is a native of Ocaña, and flowered with G. R. le Doux, Esq., of East Molesey, in March of the present year.—*Kew Bulletin*, p. 140.

SPIRANTHES OLIVACEA, Rolfe.—A north Peruvian species, with olive-green leaves, marked with a few white spots, and light olive-green flowers tipped with faint pink, and a whitish lip.—*Kew Bulletin*, p. 141.

Foreign Correspondence.

London Letter.

TREE-PRUNING.—I refer to this subject because two American gardeners who lately visited England publicly found fault with what is done in good gardens here to keep young trees shapely. There are, apparently, people who take an interest in hardy trees and shrubs who object to pruning of every kind, holding that all plants should be allowed to grow their own way from the seedling stage to maturity. To prune, they say, is to interfere with nature and to destroy the distinctive character of the tree. With plants growing under natural conditions there can be little need for the cultivator's interference, but the conditions of every garden must be more or less unnatural for the bulk of the plants grown in it, and for them the gardener's art must be exercised. In every badly managed garden one sees crippled, one-sided, rickety, misshapen trees and shrubs which are distressing enough to the man who looks for health, vigor and true form in all the things of the garden. I know that unless young trees in the garden are looked after—that is, made to grow upright, form a backbone and keep in balance—the bulk of them will soon grow otherwise. Many people who are responsible for trees pay no attention whatever to their development, leaving the branches to form and take whatever direction they please, with the result that they often grow into something totally unlike what they are under favored natural conditions. My view is that the man who allows his young trees to grow one-sided, or the lateral branches to develop out of all proportion to the leader because he considers it an outrage on nature to prune, is just as wrong as one who would allow his child to become bow-legged for want of a little support, or round-shouldered for want of gymnastic exercise. Even nature will produce cripples, but we want none of them in the garden. To keep a tree shapely and in proper balance by judicious pruning is one thing; to clip it into a form unlike what it assumes naturally is another. There must be pruning, a good deal of it too, in all well-kept gardens.

PRUNING CONIFERÆ.—In many gardens coniferous trees become thin and scraggy owing to the excessive and uneven growth of the lateral branches. This, we find, can be rectified by pruning, the long, thin branches being shortened, in early spring preferably. It is surprising how soon the trees right themselves under this treatment, the "back" growth produced by the cut branches and the better development of the shorter ones filling up and furnishing the tree in a season or two. All conifers, both indoors and out, are improved in this way.

SCHOOL OF FORESTRY.—There has been some talk of a school of forestry for England for some years, and now at last it is announced that something of the kind is to be started in the Royal Botanic Garden at Edinburgh. The prospectus states that the scheme is intended to offer an opportunity to gardeners and foresters to study the sciences underlying the practice, as well as the principles of horticulture and forestry. It is proposed to extend the course over two and a half years and to find employment in and around Edinburgh for men desirous of taking advantage of the scheme, so that while supporting themselves by the practice of their profession, they could continue the course of special study at the Botanic Garden at such times as shall not interfere with the usual hours of labor. There will be no charge for the course. Only practical gardeners

and foresters are to be allowed to share the advantages of this scheme. There has been something of the same kind in operation at Kew for a considerable period, but it is limited to the young men employed in the Royal Gardens. They are expected to go through courses of lectures on physics, chemistry, systematic botany, geography, etc. In the winter they form a mutual improvement society for the purpose of reading and discussing essays upon horticultural subjects.

BOUILLIE BORDELAISE AND POTATO DISEASE.—Experiments, with a view to testing the value of Bordeaux mixture as a fungicide, have been made this year by Mr. H. F. Moore, for Messrs. Carter & Co., of High Holborn, and a report of the results furnished by them for publication. Last year similar experiments were made by Messrs. Sutton & Sons, Reading, with results which, on the whole, were unfavorable to the Bouillie Bordelaise as a cure for potato disease.

The following table gives the totals of the two duplicate experiments :

	Dressed plots. Cwt. qrs. lbs.	Undressed plots. Cwt. qrs. lbs.	In favor of dressed plots. Cwt. qrs. lbs.
Weight of sound tubers,	58 0 0	39 2 10	18 1 18
Weight of unsound tubers,	— — 11	6 3 11	6 3 0
Total yield,	58 0 11	46 2 4	11 2 7

It will thus be seen that in whatever aspect the experiment is looked at it is in favor of the dressing by the bouillie bordelaise. So far as sound tubers are concerned, the yield is about two tons per acre more than in the undressed portion (the two plots being less than half an acre), while the quality of the tubers is better.

The last meeting of the Royal Horticultural Society produced few plants of interest. A specimen in flower of Mr. Sturtevant's *Aristolochia Gigas*, grown in a six-inch pot, was the chief attraction. It was awarded a first-class certificate and the regret expressed that something better

Fig. 82.—Live Oak (*Quercus Virginiana*) in St. Augustine, Florida.—See page 483.

The report of Mr. Moore, however, is exceptionally favorable. I quote the following from it :

The experiment was made on a field of a little less than an acre of potatoes, which were planted in ten long double rows on April 8th, the drills being thirty-six inches apart. The whole piece was divided into four equal parts, of which the first and third were dressed with the mixture, and the second and fourth left undressed. The strength of the mixture was as follows: 22 lbs. of sulphate of copper, 22 lbs. of unslaked lime, and 100 gallons of water, this being the quantity necessary for an acre of potatoes. For the purposes of the experiment the first and third quarters were dressed with the mixture on July 11th and August 2d, and the second and fourth left undressed. The mixture was applied by the Antipest, the new knapsack distributor, invented by Mr. G. F. Strawson, which did the work admirably. On the second occasion, a German machine was also tried, this also doing good work. The mixture was applied thoroughly on both surfaces of the leaf. The disease appeared early in September in the undressed portions, and on Thursday and Friday, September 15th and 16th, a party of leading agriculturists and horticulturists assembled to see the final results of a trial which has created considerable interest.

could not be done to mark the high opinion of the plant formed by the committee. Two varieties of *Cattleya*, one called *C. Statteriana* and the other *C. aurea*, var. *Statteriana*, both remarkable for the small amount of crimson on the labellums, were shown by Mr. Statter, and Messrs. Veitch showed a new hybrid *Cattleya* named *Minucia*, which they had raised from *C. Loddigesii* and *C. labiata*, var. Messrs. Linden, of Brussels, sent two *Cyrtopodiums*, one named *C. macranthum*, having yellow flowers very similar to those of *C. cardiochilum*, the other named *C. Aliceæ*, with white flowers spotted with dull red. *Pteris nivalis*, a seedling form of *P. Victoriae* with broader pinnæ than the latter, received a certificate. Two large-podded Runner Beans, named respectively *Hill's Prize* and *Prize Winner*, were awarded first-class certificates, as also were four *Kidney Potatoes*, namely, *Reading Giant*, *Mary Anderson*, *Quantity and Quality* and the *Canon*. We have too many kinds of *Potato*. I grow two, which cannot be beaten here, *Early Rose* and *Magnum Bonum*.

Cultural Department.

Tomatoes as a Summer Greenhouse Crop.

VERY many garden crops are suitable to greenhouse cultivation, but the commercial grower is limited to those which will pay, and the decision of this question depends very largely on locality. In our large cities Cucumbers, Tomatoes, Cauliflower, and even other vegetables, can be grown with profit, but the kind of crops and their succession must depend on various circumstances. A recent bulletin of the Ohio Experiment Station, which is situated at Columbus, explains why they find it necessary to adopt a course which is quite different

the same is true of Beans. Cauliflower would not pay at the prices which can be obtained, but Asparagus, Pie-plant and Dandelions, although they do not command large money returns, can still be grown to advantage, because they utilize the space under the benches. Mushrooms, too, can be grown under the benches where there are no pipes, and this is a profitable crop.

This cultivation of Tomatoes in the greenhouse for spring and summer is not altogether novel, but it is not very widely practiced, and therefore we condense from the bulletin alluded to the report of Mr. E. C. Green, the assistant horticulturist of the station, which details the methods of cultivation. It seems probable that the system could be adopted in other places

Fig. 83.—Live Oak (*Quercus Virginiana*) in St. Augustine, Florida.—See page 483.

from that followed in other cities. The Lettuces which are most profitable there are Simpson's and Grand Rapids, both belonging to the non-heading class.

Two crops of Lettuce are taken from the beds, and the houses are then occupied by Tomatoes late in the season, when Lettuce cannot be grown profitably. The Tomatoes, if forced in winter in large quantities, cannot be sold to advantage, but in late spring and early summer they will bring prices almost equal to those which rule in midwinter, and the houses are occupied when they would yield nothing more valuable. It may be added here that Cucumbers can be grown in the place of Tomatoes, but they are less profitable. The quick-growing Turnip-rooted Radishes are fairly remunerative, and

near medium-sized city markets with profit. The house which is used for Tomatoes is occupied in the winter by other plants, while the Tomato-plants are kept in as small a space as possible. As a rule, vegetable houses are empty about the middle of May, when the last crops of radishes and lettuce are taken off, and after this time they can be used with a nominal cost for fuel, and no extra expense for filling benches with soil, so that altogether they make a rather inexpensive crop.

It has been the experience of Mr. Green that these house-grown Tomatoes have been in constant demand. In the midst of the strawberry and raspberry season tomatoes sold at fifteen or twenty cents a quart, which is twice the price of berries. When tomatoes began to come from the south it did not

interfere with the sale of the tomatoes from the greenhouse, because they were of such superior quality. The seeds of Tomatoes should be sown about the middle of December if the plants are to be ready to set in beds by the middle of March, or as soon as the crop of lettuce is out. The seeds should not be sown earlier than this, or the plants will become too large or injured by crowding. The plants need warmth and sunlight, and should be kept in a warm part of the greenhouse and never allowed to be chilled. Although they will thrive with less water than many other plants, the soil should not be allowed to get dry, while excessive watering should always be avoided.

After the plants are furnished with their second or third leaves they should be transplanted at least once more before they are large enough to be placed where they are to fruit. At the first transplanting they should be set two inches apart each way and twice as far at the second transplanting. When they are set where they are to stand finally they are planted directly in the soil, eighteen or twenty inches apart each way. Large pots and boxes, which are recommended for forcing winter plants, have been tried for these spring and summer fruiting Tomatoes, but they seem to have no advantage. The last transplanting should be done some time in March, for after the middle of this month the benches cannot be used for Lettuce profitably as the houses are liable to get too warm, and the abundance of Lettuce from hot-beds brings the price down. But when the Tomato-plants are set out, if good Lettuce-plants are set between them a fair crop of the latter may be grown before the Tomato-plants reach any considerable size. After the Lettuce is off, the Tomatoes should have the entire ground and should have a good mulch of fine manure, which will assist in holding water that is applied to the bed. The plants should be trained to one or two stakes, and a wire or string is a preferable support to stakes. The top may be made fast to the rafters and the bottom anchored by sharp wooden pins driven into the bottom of the benches or by wires stretched across near the surface of the ground. They must be tied to these upright strings or wires frequently as they grow.

Pruning is important not only because it increases the size and earliness of the fruit, but in order to get the largest yield possible in the smallest space and to keep the plants in the best shape. It is not the nature of the Tomato-plant to confine itself to one stalk, and when compelled to do so its efforts to grow side branches are persistent. Not only will sprouts come out of the axil of each leaf, but the ends of the blossom-stalks will develop into branches, and even the upper surface of the main vein of the leaves will send out sprouts. All of these must be taken off or there will be a tangled mass of vines if the plants are close together. The varieties which do well out-of-doors are the ones which will do well in the house for spring and summer. The best purple kinds that have been tested are Acme and Beauty. The best red kinds are Perfection and Paragon. The Lorillard, which is recommended so highly for winter-forcing, has not done so well under this system as some others. The early rough varieties are not desirable since pruning seems to make them more irregular. After a thorough trial the Atlantic Prize, one of the best of this class, has been discarded, and so have Hundred Day and King of the Earliest. The Dwarf Champion has some good qualities since the plants can be set closer together and nearer to the glass than other varieties. The first fruits that set are of fair size, while on some of the other varieties they are small. It is difficult to prune, however, because the heavy leaves hide the sprouts and it does not yield heavily.

Garden Annuals.

ANNUALS are more generally a part of the flower-border now than ever before in small gardens as well as in larger ones. This class of plants is popular because they do not require to be cared for through the winter, because there is a larger variety to choose from than formerly; and in most cases, also, with seeds sown where they are to flower, success is almost sure. Where a greenhouse, or even a hot-bed, is at command, a fine display may be produced with very little outlay. Home-grown seeds, carefully selected, may be planted with success, but seeds of first quality can be bought at low prices, so that there is no advantage in saving seed except in the case of some special varieties it may be desirable to perpetuate.

Among annuals recently introduced are the Marguerite Carnations, a most useful race of plants that give good double sweet-scented flowers the same season they are sown. There seems to have been too great demand for these seeds, and the producers have not given themselves time to weed out the

single-flowered kinds. This year more than half the plants have produced single flowers, a much larger percentage than when this strain of Carnations first became known. Our season here is too short for them unless they are raised early under glass and hardened off previous to planting out early in summer. I find it best to sow them in January, when they will flower soon after midsummer, and last until frost.

Coreopsis Drummondii is an annual species of great service for a continued display. The flowers are of good size, though not so large as those of *C. grandiflora*, but they are much more numerous, and may be cut for several months. This *Coreopsis* is also useful for winter-blooming; if sown early, and transplanted into seven or eight inch pots, it gives good returns all through the early spring months. The same applies to the yellow Corn-flower (*Centaurea suaveolens*), also desirable for cutting. Pot-culture suits both these plants best; in benches they are apt to grow too vigorous toward spring and to wilt during sunshine. *Coreopsis Drummondii* and *Centaurea suaveolens* may both be sown in the open ground at the usual season for a display in summer and late in autumn.

An annual climbing plant which has given us much satisfaction is *Dolichos Lablab*, the Hyacinth Bean. The panicles of flowers are very showy, both the purple and white varieties, but the clusters of seed-pods are a lasting ornament, as they turn a rich dark purple and keep this color until killed by frost. We sow the seeds where the plants are to remain during the summer; they grow rapidly and flower and fruit freely in a sunny position. In our section *Cosmos hybridus* does not flower in the open air as in more favored states, but is grown in pots and taken into the greenhouse in the fall, where it yields a harvest of beautiful long-stemmed flowers in the dull autumn months, when they are most acceptable. *Cosmos* is best sown in May; it flowers as soon and is not so tall as if sown earlier, and the results are as good; these plants are strong growers and require an abundance of food and moisture. Under pot-culture it is necessary to give these requirements several times a week. If this care is not possible they may be planted out in summer, lifted in the fall and planted in large pots.

Solanum ciliatum is a beautiful berried plant for winter decoration. When well grown the plants are as ornamental as a small Orange-tree laden with fruit, and much easier to obtain. Seeds are now offered in trade lists and should be sown early under glass and grown in pots during the summer. Our plants are in eight-inch pots and average about thirty fruits to a plant. These are a bright orange-scarlet, from one to two inches in diameter and grow along the under side of the branches. The shoots are pinched once or twice during the growing season to bring them into shape. The plants are now available for decorative purposes and may be used all winter, as the fruit is very persistent even after the foliage has fallen. It should be added that the specific name of this plant refers to an abundance of sharp spines on both sides of the leaves and on the branches.

For a bold ornamental foliaged plant for outdoor planting in summer, the new Tobacco plant, *Nicotiana colossea*, of seed catalogues, is much the best of its kind. The correct name is *N. tomentosa*. It is a colossal species that requires liberal treatment to do it justice. Our plants were raised late, and for this reason have not flowered this season, although they have grown about six feet high and show well in a large border. As an isolated plant *N. tomentosa* would be found useful, but it is too large for most borders. This giant Tobacco plant should be sown early under glass and planted out when a good size. It will then probably flower here as it has at Kew and elsewhere in Europe.

South Lancaster, Mass.

E. O. Orpet.

The Chionodoxas.

AT this time, when bulbs are being bought, attention may be called to the *Chionodoxas* as among the most attractive plants flowering early in the year. They should be grown in clumps and masses in the front border, where they succeed the Snowdrops. The bulbs are small and perfectly hardy, and increase rapidly, so that it is difficult to clear the ground from them when they are once established, as the small tubers are not easily found without sifting the soil. The *Chionodoxas* are not rampant growers, however, and do not endanger other plants. They are low-growing plants with narrow leaves; a radical-curved scape bears from three to ten flowers, which are usually erect.

Chionodoxa Cretensis is an old introduction. The flowers of this species are small, and in neither of its two varieties, blue and white, attractive in color. It is not often grown in gar-

dens, being neither effective nor interesting except in a collection. The popularity of *Chionodoxa* dates from the introduction of *C. Luciliae* from Asia Minor. This species has all the points of a good garden-flower, and is one of the brightest gems of the spring-time. The flowers from collected bulbs vary considerably, but good forms have flowers over an inch in diameter, with light blue tips and white centres. This species, which is also known as *C. Forbesii*, produces flowers more freely than the other kinds.

Mr. Edward Whittall, of Smyrna, during his hunting expeditions discovered that there were on the Taurus Mountains many bulbous plants unknown to cultivation, and, with an Englishman's natural fondness for flowers, organized a systematic search of the hills for bulbs which were likely to prove attractive in gardens. This work is carried on by the natives under direction. The country is in a shocking state of anarchy, even within sight of Smyrna, and the work is done at considerable risk. To Mr. Whittall we owe the following varieties, which have been introduced by his efforts: *C. Sardensis*, a dark blue-flowered kind, which has met with appreciation, the color being the blue of the interior of the cup of *Scilla Siberica*. As the *Scilla*-flowers are duller on the outer cup, *C. Sardensis*, with its upright flowers, is superior in its intensity of blue as seen in the borders. *C. Tmolusi* is a species collected on a height of this name, but appears to be a local variety of the *Luciliae* type, having a large white eye such as is often found in the type.

Chionodoxa grandiflora, or *gigantea*, was next found, and is a variety of much beauty, though it has met with slow appreciation. It has a flower somewhat larger and with broader petals than *C. Luciliae*, and the color is an opaque blue. The eye is very small and white. In my border the plants have shown only two or three flowers on each scape. The figure of this *Chionodoxa*, in a recent number of *The Garden*, is not satisfactory; the color is too deep, and linings are shown which do not appear in the flowers. Among bulbs of *C. Luciliae* some are occasionally found which give pure white, or rose-colored, flowers. The former are especially pure in color, and are very charming. Unfortunately, these are among the rarest of bulbs, and are not in the dealer's stock. This season Mr. Whittall has sent out a new species, *C. Alleni*, which he says is the finest yet found. As it comes without description, we trust it to the border with pleasant anticipations of a new charm to enjoy as the lengthening days of another spring bid it welcome to a new home.

Elizabeth, N. J.

J. N. Gerard.

Seasonable Notes.

CHRYSANTHEMUMS will naturally have a prominent place in the garden-world during the weeks to follow, and there will be many magnificent blooms at the exhibitions throughout the country; but the amateur cultivator must not look for similar flowers on the same varieties in his own collection, unless his specimens receive the same attention.

To secure the immense flowers seen at exhibitions the strength of the plant has been thrown into one or two blooms by a careful system of disbudding and feeding, and the foliage kept clean and free from insects. Unless the flowers are intended for exhibition, greater satisfaction will be had from more naturally grown plants, especially for conservatory and house decoration, and a large mass of reasonably good flowers will prove more effective than a few spindling specimens crowned with a single blossom that some one has sarcastically described as resembling "a variegated mop." Some disbudding should be practiced, however, as there is usually a superabundance of buds on most varieties, and tying and training should also receive some attention, without disfiguring the plants with a forest of stakes.

Where the conveniences are at hand, the vaporizing of tobacco extract is the most cleanly and effective method of removing aphides from *Chrysanthemums*. If this cannot be done, fumigating with tobacco-stems must be resorted to, either method being used at frequent intervals before the buds begin to open, in order to keep the plants thoroughly clean. Feeding with manure-water should also be persisted in, but with pot-plants care must be taken to keep the drainage open or the plants will soon suffer.

Among the earliest varieties I have noticed this season are *Eldorado* (Waterer), an excellent yellow of sturdy growth and fine foliage, and *Ivory* (Harris), a particularly good white either as a pot-plant or for cutting, being of medium size and excellent habit. Outdoor *Chrysanthemums* may be preserved from frost long enough to allow the full enjoyment of their flowers by covering them at night with water-proof muslin

stretched over a light frame-work of wood. The muslin may be procured from almost any seedsman for from six to ten cents per yard, according to the grade used. The present season has been a somewhat trying one for many outdoor operations. The lifting of stock from the open ground, as *Violets*, *Carnations* and *Bouvardias*, has been attended with some difficulty owing to the dry weather, but, as already noted in *GARDEN AND FOREST*, the success of this operation largely depends on the care with which the plants are treated after they are brought indoors.

It is desirable to grow a few Fig-seedlings (*Ficus carica*), in readiness for bedding out next season. In a mixed bed of foliage-plants these have a pleasing effect, the foliage of the Figs being both large and handsome, and seldom attacked by insects to any great extent. The experience of the past summer tends to confirm the value of *Crotons* and *Acalyphas* as bedding-plants, at least in this latitude; but it should also be remembered that while the *Crotons* will flourish in a greenhouse temperature of seventy-five to eighty degrees, it is not well to take the plants so grown directly from so warm a house and plant them out. When properly hardened off they are, however, among the most effective foliage-plants for outdoor decoration.

The *Crozy Cannas* continue to add to their fame with each succeeding season, and among the newer varieties *Alphonse Bouvier*, a green-foliaged variety, with large bright crimson flowers, takes a prominent place. *Paul Marquant*, also, is a fine variety, with some resemblance to *Antoine Crozy*, the flowers frequently over four inches in diameter. *Capitaine Suzzoni* is perhaps the best of the spotted type; the ground-color is yellow, over which is spread a profusion of red spots.

Correspondence.

Fruits of Eastern Asia.

To the Editor of *GARDEN AND FOREST*:

Sir,—I have read, with great interest and pleasure, the notice on p. 438, with an illustration of a Chinese Peach grown from seed at the Arnold Arboretum. I was also pleased to note Professor Sargent's remark, "that the Peach is now believed to be a native of China." The result of this experiment, so far as it shows a superior hardiness in this Chinese seedling Peach, is an argument that in transferring the fruits of the old world to America there must be taken into account the difference in climatic peculiarities between the eastern and western sides of these two continents. I believe that the more this subject is studied the more reason we shall find for seeking a renewal of our tree-fruits for eastern America from among those of eastern Asia. Professor Budd, of the Iowa Agricultural College, has been experimenting in this line, and the *Shense Apricot*, which originated from a seed sent to Professor Budd from a missionary station in northern China, has proved to have remarkable vigor and hardiness, and is being now quite extensively planted. I hope the resources of the Arboretum may be more extensively availed of to import the Chinese and Manchurian tree-fruits as well as other plants from that region.

I notice also Professor Bailey's article on scab-proof Apples, on p. 442. There is a certain amount of reason, undoubtedly, in the apprehension that new and apparently scab-proof fruits will not retain that characteristic long. That has been the case certainly with many of the seedlings which have originated in our northern states. They do well for a while, but in time fall a prey to disease. But it should be borne in mind that these seedlings are all from the old stock of west European varieties, and although such seedlings show some accommodations—some approach to what we call acclimation—and although nearly all our profitable Apples are of this class, yet there is a latent weakness in them all. It will not take many generations to advance the work to a point which we may reach much sooner if we extend our researches among the orchards of north-eastern Asia.

All this will, of course, take time, and the older among us can hardly expect to reap any personal advantage from these efforts to introduce a better race of tree-fruits into our country. It is very evident that all the tree-fruits of western Europe find themselves quite at home in western America. It seems at least equally probable that the tree-fruits of eastern Asia will find a congenial habitat in eastern America, and these are considerations that especially urge growers who find themselves located in the most unfavorable localities, where our old stock of tree-fruits are complete failures, now to pioneer the work of research. In the cold north and in that region of extremes,

the Mississippi Valley, the evils referred to are the more instantly pressing; but it is quite plain, from what Professor Bailey tells us, that in our most favorable localities on the eastern slope, where at first the finest fruit was grown without even ordinary care, it is now impossible to grow it regularly in marketable quality without resorting to the constant use of fungicide as well as insecticide spraying.

I certainly do not desire to take upon myself the rôle of opposition to the use of either fungicide or insecticide spraying. I am using both in my own gardens and orchards; but the use of them, and the necessity for that use, only make me the more anxious to obtain and test any and all varieties of fruit-trees and plants, adapted to our locality, which show exceptional resisting power against any and all the ills to which orchards and gardens are heir. Having attained this, the heavier portion of the task is completed, and we have only to concern ourselves with the details of the work. But so long as we have to contend with fundamentally unsound material our task becomes so difficult as to greatly discourage its prosecution.

The Apple-scab Again.

To the Editor of GARDEN AND FOREST :

Sir,—I have recently made a trip through southern Michigan, where the apple-crop is probably the smallest ever known. Everywhere the trees present a sorry appearance. The foliage is small and curled and brown, and even at a distance of half a mile the orchards appear to have been scorched with fire. Many trees are so badly affected that they have hardly cast a shade all summer. In some orchards I notice green tips on the branches, marking the renewed vigor produced by the late rains. Everywhere the apple-growers are discouraged, and they are wondering if the trees can survive such injuries. These are the same troubles as those which overran western New York in 1890, and which caused such widespread alarm. But in 1891 the New York orchards gave a fair crop of fine apples, and here is some consolation for the Michigan people. But the injury must seriously shock the trees, and, aside from the loss of this year's crop, the mischief must be considerable.

All this serious leaf-trouble is to be laid to fungi, which were enabled to develop with fatal rapidity in the wetness of last spring. It is probable that these fungi even caused much of the dropping of the little fruits themselves. It is evident that most of the dropping of the flowers is wholly natural, and to be expected, for, as a rule, only one fruit sets in a cluster of flowers. In most tree-fruits the fruitage is necessarily much smaller than the full bloom. Later on the drought came, and the injury added to the troubles from the rains and the fungi was complete. The orchards in the older part of Michigan now present a sad appearance. In northern Michigan, in the Traverse region, the apples are unusually good this year, and I am told that the rains did not begin there until after the fruits were well set.

The chief fungus concerned in this scourge appears to be the fuscladium, or scab-fungus, which causes the familiar black scab-like spots on the fruit, as well as a blight or mildew of the foliage. The scab-fungus injury upon the leaves usually appears as grayish or gray-brown blotches, appearing to rest upon the surface, and not completely killing the tissue beneath it. But there is another injury of the leaves characterized by a complete dying of the tissue, so that the leaves become winter-brown in patches or along the edges. This injury is possibly due to a *Phyllosticta*. Professor Beach, of the New York State Experiment Station, tells me that still a third fungus appears to be concerned in this Apple-leaf blighting. The occurrence of two or more fungi in these scourges has been mentioned several times by recent writers, but the exact part which each plays in the destruction of fruit and foliage has not been determined. It seems to be generally agreed that the scab-fungus is the most mischievous.

In connection with the discussions now running in GARDEN AND FOREST concerning the relation of certain varieties of Apples to the scab, it may be worth while to make a record of the behavior of the blight in my father's orchard in south-western Michigan. Some of the varieties here recorded are represented by a single tree in the orchard, but the most important varieties are in good number, especially Rhode Island Greening, Baldwin, Stark, Northern Spy, Esopus, Spitzenburg, Golden Russet, Talman Sweet and Swaar. I have thrown the varieties into three categories as well as I can: 1. Those very badly injured, which for weeks have hardly cast a shade, and in which none of the leaves have reached normal size, the trees presenting no green color. 2. Those much injured, in which some of the leaves reach normal size and the trees present a

somewhat green appearance, but none of the leaves are free from conspicuous injury. 3. Those little injured, in which all the leaves attain normal size and the tree looks full, but all the leaves are marked by scab. I found no varieties which I could put into a fourth class, to be characterized by no injury whatever. It remains to be said that all varieties without distinction, save, possibly, a few trees of Flower of Genesee, failed entirely to produce fruit, although they all blossomed full.

1. Varieties very badly injured: Baldwin, Belmont, Bunker Hill, Chenango, Early Harvest, Esopus Spitzenburg, Golden Russet, Grimes' Golden, Jonathan, Newtown Pippin, Nickajack, Northern Spy, Rambo, Rhode Island Greening, Paw Paw, Siberian Crab, Stark, Summer Queen, Surprise, Swaar, Tompkins King, Westfield, Seek-no-further, Williams, Yellow Belle-fleur.

2. Varieties much injured: Beehouse, Fall Jenneing, Fall Pippin, Holland Pippin, Stark, Stode's Birmingham, Swaar, Talman Sweet, Transcendent Crab.

3. Varieties little injured: Baldwin, Cabashea, Cloth of Gold, Cogswell, Egg-top, Flower of Genesee, Northern Spy, Red Astrachan, Red Canada, Rhode Island Greening, Roxbury Russet, Sweet Bough, Transcendent Crab, Twenty Ounce.

It will be observed that some varieties occur in two lists. The Baldwin, Northern Spy and Rhode Island Greening, for instance, occur in the worst and best lists, yet the trees, so far as could be seen, were equally exposed to untoward circumstances. Some Baldwins were almost defoliated, and none of the leaves had reached more than half-size, while others in the same orchard might have been passed by the casual observer for trees in perfect health. Some young and vigorous Baldwin-grafts were scarcely injured. The blight appears to affect the various varieties differently. The foliage of Beehouse and Sweet Bough, for instance, presents a thick and conspicuously curled appearance, much like the leaves of Snowballs which are attacked by aphides.

At the recent meeting of the American Horticultural Society in Chicago several persons spoke of the comparative immunity from scab of some of the hardier Russian Apples, and it seemed to be a prevailing opinion that a more or less immune race of Apples can be bred from them. I hope that this prophecy may come to pass. It is an interesting field, but I cannot rest my faith entirely upon it for ultimate and permanent results. It is certainly expedient to extend the operation of spraying at the same time that we are striving for resistant varieties. In years like the present, the best efforts are likely to give indifferent results, but I believe that spraying every year will lessen the evils of the bad years.

Cornell University.

L. H. Bailey.

Legislation against Injurious Insects.

To the Editor of GARDEN AND FOREST :

Sir,—The editorial on "Legislation against Injurious Insects and Plant Diseases," in your issue of September 28th, is both important and timely, and merits the careful consideration of every association of agriculturists in all parts of the Union. In New Jersey there is already a very strong feeling among the farmers who are following experiment station advice, that something should be done to protect them from the neglect of their less progressive neighbors, and the subject will be agitated in the county boards and probably also in some of the state societies during the coming winter.

Allow me to give two examples of the necessity of some action. The pear-midge (*Diplosis pyrivora*) has been, quite recently, introduced into New Jersey, and is slowly spreading. It reached New Brunswick in 1891 and settled in a neglected orchard not far from town. The owner of this orchard has other business and simply allows it to take care of itself. The trees are old, diseased, infested by insects and, except in rare cases, produce no marketable fruit. Closely adjoining is a Pear-orchard, whose owner uses all means to get fine, perfect fruit. The trees are healthy, are kept free from disease and insects by the intelligent use of the fungicides and insecticides, and bear heavy crops of the finest varieties of pears—fruit that takes premiums annually wherever exhibited. In the spring of 1892, a few midges found their way to this orchard and a few Pears were infested. Vigorous means were at once adopted to destroy them; but what is the advantage? In the neglected orchard close by, at least fifty per cent. of the fruit was infested early in the season, and thousands of midges will mature there next spring and will not all remain in the old orchard. Despite all preventive measures, the good orchard will suffer and the owner will lose a considerable sum, simply because his neighbor will not care for his own property.

In Atlantic and Cumberland counties, large tracts are de-

voted to Blackberry culture, and much fruit of fine flavor and good size is shipped to northern, eastern and western markets, as well as to New York and Philadelphia. The most serious enemy to Blackberry culture is the red-necked cane-borer (*Agilus ruficollis*), which is yet very easily controlled by cutting out the galls when pruning in spring, and burning the cuttings. But of what avail is it to the intelligent grower if he cuts out all the galls in his field carefully, if his neighbor allows those in his field to stand? For several years last past this insect has steadily increased in number, and a tax of fifty per cent. on the crop of the two counties is a low estimate of the injury caused in 1892. On many acres the crop was not considered worth picking, and the fields were allowed to take care of themselves. They have done that so well that early in September I found many of them in which every new cane was galled, and in some canes as many as ten and even twelve galls were on a single cane. The host of insects that will develop there next spring will not find canes for one-tenth the females that will desire to oviposit, and they will fly to the neighboring well-kept fields, and will levy their tax on the innocent and careful grower as well as on the guilty careless one. There are hundreds of acres scattered in these two counties which will, next year, produce more insects than Blackberries, and which, for the benefit of others, should be utterly destroyed this winter.

It is a maxim of the common law, that every man must so use his own property as not to injure his neighbor or others; but it is a matter of very grave doubt whether any attempt at redress under this maxim would be successful under the present circumstances. Certain it is, that there is no justice in allowing one careless individual to impose a heavy tax on all his neighbors. A man who raised foxes and turned them loose in his neighbor's chicken-yards would be brought up with a round turn very suddenly. There is no reason that I can see why one who willfully breeds insects to infest his neighbors' orchards stands on a different footing.

I hope you have not said your last words on this subject.
Rutgers College, New Brunswick, N. J. *John B. Smith.*

Exhibitions.

Fruits and Vegetables at Boston.

THE fruit and vegetable show of the Massachusetts Horticultural Society, held at Horticultural Hall in Boston during the first week of this month, was, in point of exhibits, a noteworthy success. The somewhat slender attendance was a new proof of the lack of public interest in the efforts of specialists who have given so much study and time to improving the quality and beauty of table fruits and vegetables. It is to be regretted that the efforts of our best horticultural societies meet with so little appreciation.

The fruits at the recent exhibition occupied the entire upper floor of the building, and the vegetables were arranged in the spacious hall beneath. Apples were largely represented, and some idea of the extent of this display may be gleaned from the fact that no fewer than two hundred and seventy dishes, illustrating about thirty varieties, and averaging twelve specimens to a dish, were placed in competition. The contributions of pears were larger still. There were two hundred and ninety-five dishes, each containing twelve samples. Some twenty-eight varieties were shown in their finest form, so that the display was as beautiful as it was extensive.

Grapes, especially the native kinds, were plentiful and of good quality. The state Agricultural College at Amherst and Mr. Benjamin G. Smith, of Cambridge, were the principal exhibitors of domestic varieties, and these growers, with several others, supplied the total of 165 plates of six bunches each. The Amherst exhibit contained sixty-one distinct varieties, and it afforded grape-growers an opportunity for selection which comes too seldom. The first prizes for foreign grapes went to Mr. J. Monteith, gardener to Geo. A. Nickerson, of Dedham, and Mr. John Ash, gardener to Mrs. J. W. Clark, of Pomfret, Connecticut. The former was first in four classes, with Gros Moroc, Golden Hamburg, Black Hamburg, Ali-cante, Buckland Sweetwater and Muscat of Alexandria, and the latter in one class, with Black Alicante, in every respect the best grapes in the hall.

Mr. George S. Curtis, of Jamaica Plain, was an easy first in Quinces. Some splendid orchard-house examples of the Late Crawford Peach were shown by Mr. Robert McLeod, gardener to D. B. Fearing, Esq., Newport, Rhode Island; Mr. N. D. Harrington, of Somerville, secured first for the same variety grown out-of-doors, and a like honor was conferred on

Mr. W. D. Hinds, of Townsend, for the Crosby. Plums were of indifferent quality, and prizes were given to Mrs. Mary Langmaid, of North Somerville, and Mr. E. S. Grant, of Concord. Mr. C. Terry, of North Weymouth, was the only exhibitor of Cranberries, and Pine-apples were contributed by Mr. Jackson Dawson, of the Arnold Arboretum. Some curiosities were furnished in the form of a branch of the Sheldon Pear, with a close cluster of seven fully developed fruits at the extremity, and in a dish of Endicott pears from a tree imported from England by Governor Endicott in 1636.

The vegetables, embracing all the best seasonable sorts, were numerous and of first-class appearance. The miscellaneous exhibits included a collection of hardy flowers from the Harvard Botanic Garden, some vases of creditable single and double Dahlias from C. E. Josselyn, of Framingham, four dishes of very fine flowers of tuberous-rooted Begonias from Francis Brown Hayes, Esq. (Mr. James Comley, gardener), of Lexington, and a nice group of *Streptocarpus*, from Mr. Wm. Martin, gardener to Nathaniel T. Kidder, Esq., of Milton. Mr. Kidder was successful in obtaining the first prize for a collection of flowers of forty herbaceous plants, the Shady Hill Nursery Company, of Cambridge, being second.

Recent Publications.

Dictionary of Botanical Terms. By A. A. Crozier. Henry Holt & Co.

The science of botany has developed on so many lines within the last twenty years that there has been necessity of creating a great many new terms, and it is also true that many of the old ones have been practically abandoned, and inasmuch as it has been almost a score of years since any English dictionary of botanical terms was published there is abundant demand for a book like this. The modern study of structural and physiological botany is responsible for many of the newer terms, but improved practice in agriculture and horticulture, as well as the advance in the sciences on which both these arts are based, has also made many new words necessary. This book of Mr. Crozier's seems to be very complete in both the practical and scientific sections and will be a welcome addition to many reference libraries.

Fruit-culture. By W. C. Strong. Rural Publishing Company.

This little hand-book was first published seven years ago, and was intended to furnish condensed and simple directions for the average owners of homesteads who wish to raise a few fruits for home use. So great, however, has been the advance in the practical methods of protecting crops from insects and fungi that a book seven years old is quite behind the times. Mr. Strong has, therefore, prepared a new edition, in which he has attempted in a concise way to embody the results of recent experience with various insecticides and fungicides, and the methods of applying them. Of course, in a brief two hundred pages, nothing like extended description of varieties of different fruits can be looked for. The book contains, however, in a very compact form, the best methods of cultivation for each separate fruit and some descriptions of the best varieties, with illustrated directions for propagating trees from the seed, by cuttings, by layers, by grafting, etc. The book is not intended to supersede the more exhaustive treatises which have been written for those who wish to grow fruit on a large scale, but for the inexperienced cultivator Mr. Strong's book will be welcome and helpful.

Notes.

The white form of *Plumbago Capensis* is comparatively rare, but it resembles the species in almost every respect except in the color of its flowers, and the two together are admirable companions.

Mr. John Westcott, who is well informed on such matters, is reported in the *Florists' Exchange* as saying that in the neighborhood of Philadelphia there are fifty houses full of *Chrysanthemums* in excess of the quantity produced last year.

A Douglas Fir was planted in the spring of 1842 at Walcot, the seat of the Earl of Powis, in Shropshire. This spring, after it had stood fifty years, it measured one hundred and seven feet to the top of the leader, and at four feet from the ground the girth of its trunk was twelve feet nine inches.

The planting of the dunes at Blankenberghe, near The Hague, in Holland, begun on a great scale three years ago, is being steadily carried on. So successful has been the work

that in some of the places first planted certain of the selected species have already attained a height of more than six feet.

The leaves of *Spiræa prunifolia* remain on the shrub very late in autumn, but they begin to turn among the first. They change very slowly from glossy green to deep crimson, and although the plant has a more whippy habit than most of the *Spiræas*, for October coloring, it is one of the very best of shrubs.

A Portugal Laurel at Combermere Abbey, in Cheshire, is said to be at least two hundred years old, and its branches have rooted in every direction. It has the appearance of being a large mass of shrubbery instead of a single Laurel. In places it is thirty feet high, and altogether it is a hundred feet in diameter.

The leaves of the Hickory are easily scorched by frost, and, therefore, in seasons when freezing weather comes early, the foliage turns brown and withers early. But in years like this, when frosts are delayed, the leaves ripen to a clear lemon-yellow, so that the Hickory becomes fairly luminous and is one of the most striking of our native trees, which are famous for their autumn colors.

A variety of *Helenium autumnale*, named *Striatum*, has lately received a first-class certificate in England, and it promises to be a welcome addition to our late-blooming hardy plants. It is particularly interesting because of its colors. The disk is spoken of as maroon and gold, and the florets are a rich red striped with yellow. Autumn gardens contain so many composites in which the prevailing color is yellow that this variation will be a pleasant relief.

As the Memorial Garden, which lies between Longfellow's Cambridge home and the Charles River, attracts so few visitors that it is believed its commemorative character is not generally recognized, it has been proposed to make this clearer by the erection of some sort of a monument to the poet. But, as the Longfellow family does not approve of this scheme, preferring the unmarked quiet open garden, it is probable that it will not be carried out.

Some years ago an oak-trunk was found buried at a depth of thirteen feet in a sand-pit at Musselburg, Germany. After examining the strata in which it had lain, Professor Geikie decided that it was a relic of the later stone age, and must be some 6,000 years old. Yet the great trunk, which was no less than five feet nine inches in diameter, was so perfectly preserved that it was worked into an elaborate chimney-piece, which now ornaments a house in Edinburgh.

A late bulletin of the Rhode Island Experiment Station gives a word of caution to the purchasers of wood ashes. Analysis of the ashes which is sold in that state shows that they vary widely in chemical composition and fertilizing value. In some instances they were of such a low grade that farmers were advised to demand of the dealer a guarantee. If farmers would always insist on such a guarantee and order samples sent to the state experiment station, the quality of the ashes sold would soon be improved and they would all contain such an amount of phosphoric acid and potash as would make them worth buying.

At present the use of birch-bark as a writing material is merely a diversion of the tourist, but in earlier years, as we know, the Indians put it to serious service, while in Europe the bark of the White Birch was an occasional writing material before the invention of paper. In India one of the most ancient of all writing materials was the bark of the Himalayan Birch (*Betula Bhojpattra*), allusions to it being found in books 2,000 years old. To-day this substance is employed as a lining for boots and shoes, but only charms and amulets are written on it, because of its great durability. The magic words are inscribed upon a small bit, which is then enclosed in a bead of gold or silver or brass, which is worn on the person.

Since Cypress lumber is being dried by artificial means, the product is much superior and the demand for it has largely increased. Several large Louisiana mills, we are now told by the *Northwestern Lumberman*, have been supplied with steam-heat kilns, in which there is no ventilation and an extraordinary dampness of the atmosphere. In this veritable sweat-box the sap and natural juices of the timber are actually steamed or boiled out of the fibre of the wood. The bottom of the kiln is of sand, into which the drippings from the wood drop and saturate it until it is converted almost into mud. After the heating process is continued for a certain length of time the kiln is opened, the air admitted, the moisture dissipated and the lumber turned out to dry.

The *Gardeners' Magazine* for September 24th contains an engraving of the comparatively new *Polyantha Rose*, named Turner's *Crimson Rambler*, which was brought from Japan a few years ago and received a gold medal at the International Horticultural Exhibition. The growth is very robust, and in July, when the truss was selected for figuring, thousands of plants which had been budded the previous summer had made shoots ranging from six to eight feet high. The trusses are produced in succession so that the display is maintained over a considerable period. The color of this Rose is described as a glowing crimson, and the truss figured contains a mass of more than fifty flowers fully opened, besides numerous buds all closely packed in a pyramidal mass.

So few formal gardens exist in this country that it is worth while to call attention to the picture of the one connected with the old convent school for girls at Georgetown, near Washington, which is published in the *Cosmopolitan Magazine* for October. This garden, which seems to have been laid out in the early years of the century, is, if one may judge from the picture, not a remarkable one in any way, yet it shows how attractive may be a combination of naturally developed trees, with systematically arranged paths, borders, grass-plots and flower-beds. And, as has often been said in these pages, such a combination might be made as beautiful and appropriate in small grounds attached to dignified buildings as are our customary attempts at landscape-gardening on a miniature scale.

A note in one of the daily papers announces the sale to a Baltimore syndicate of the Dismal Swamp Canal for the sum of \$10,000. This famous canal connects the waters of the Elizabeth in Virginia and the Dismal Swamp with the Pasquotank in North Carolina and is twenty-three miles long. Its construction was authorized by act of the Virginia Assembly in 1787, and George Washington was its original projector. It cost \$1,500,000. The new owners propose to "improve the waterways and develop the timber-lands," which are very valuable and include tracts of Cypress and other trees of large size. With the exception of the main Jericho Canal and a few smaller passages and Lake Drummond, some ten miles in the interior, the swamp is practically impenetrable on account of the dense growth of Cane-brake.

The report of the Director of the Kansas Experiment Station contains an article on the contagious diseases of the chinch bug, which is pronounced by Professor H. T. Fernald, in *Agricultural Science*, one of the most valuable contributions to economic entomology which has lately appeared, ranking in importance with the introduction of the *Vedalia* into California. The experiments were begun in 1889, and healthy bugs placed in jars with diseased ones quickly became affected, and the field-trials showed that when a number of these diseased bugs were liberated where others were abundant the disease spread rapidly. In 1891 fourteen hundred field-trials were made, and more than three-fourths of these were so successful that the saving of the crops was estimated at more than \$87,000, or \$181 to each of the 482 farmers who tried the experiments. In the opinion of Professor Fernald this report marks the first apparently successful entrance of entomology into an almost unknown field, where much progress is to be hoped for. He believes that the cultivation of the natural enemies of our insect pests and the keeping of stocks of them on hand for shipment to infested areas is a line of work which must prove of great value. Any one who bestows a little thought on the relative advantages of insecticides applied by hand on the one side, and of parasites which are able to pursue their hosts from place to place and spread disease by infection on the other, will see that the latter is theoretically, at least, the most effectual and satisfactory.

Botany in the Agricultural Colleges.

SOME time ago Professor Bailey, in a suggestive contribution to *Science*, made a plea for a broader botany. We quoted largely from the article at the time of its publication and will only repeat that the fact complained of was the restriction of botanical science to the study of wild plants. This was natural in earlier days, when there was little attempt to apply science to cultivation, but since the theory of evolution has come to be accepted, a new purpose has been given to the study of all natural objects, and cultivated plants especially have gained a fascinating interest because they furnish such conspicuous examples of variation and heredity. The great mass of material which the multiplied species of cultivated plants afford can be made to illustrate the accumulative effect of modified environment and selection under the influence of human care as wild plants cannot possibly do. They can show within a brief period as much progression in definite lines as their wild prototypes could show in ages. This makes the garden one of the best places in which evolution can be studied. But the point which it is proposed here to insist upon is, that more and more it should be the endeavor of those interested in agriculture and horticulture to bring into practical use the facts and laws which science discloses, and make them actually helpful in the cultivation of plants. The study of botany as pure science, the investigation of the laws of plant physiology and variation under different conditions, can have abundant application in improving the quality and changing the character of economic plants as well as in developing new and better methods of cultivation. This means that not only should increased attention be given to the study of fungi and bacteria and other special branches of the science, but that more attention should be given to investigations and experiments to show how all the general truths of the science can be applied

to the improvement of agricultural and horticultural practice.

There is encouragement in the fact that the attention paid to botanical science in this country has largely increased in recent years. In an address delivered by Dr. Beal at the laying of the corner-stone of the new laboratory in the Agricultural College of Michigan he stated that in 1859 when he took his first degree at the University of Michigan there was but one institution of learning in the United States where a man was employed and paid for devoting his entire time to the science of botany. That man was Dr. Asa Gray, Professor of Botany at Harvard University, and at that time only eight weeks of daily work were required of undergraduate students, and they had the opportunity of electing about three weeks more. A very few resident graduates, from one to three at a time, pursued the science further. In a few other universities and colleges, botany filled a small niche in the general course of study, the same man usually teaching botany, zoölogy and geology in the course, and often, too, giving instructions in other branches of learning.

The increased interest and attention which the study of botany has attracted and which is seen in the numerous state and national gatherings of men of science where a growing number of subjects in this field are discussed in a broad and practical way by able men and women, is largely due to the work in the agricultural colleges and in the national Department of Agriculture. The work of practical botanists can be seen in numerous journals and transactions of these societies, in many books and bulletins. The place which the science of botany ought to fill in a well-conducted institution for the advance of agriculture is coming to be understood and appreciated, and Dr. Beal is right in saying that no agricultural college can rank among the best, where a professor of botany is required to teach any other subjects, and a simple enumeration of a few of the essentials of a botanical department according to his view will show how many-sided and comprehensive its equipment should be. It should have enthusiastic workers in the field, good collectors, persons well skilled in preparing plants for the herbarium. In agricultural colleges particular attention should be given to grasses and forage-plants, trees, shrubs and weeds. The herbarium should include specimens of cultivated plants, both those that are grown in orchards and vegetable-gardens as well as those that are grown for ornament. The laboratory should be supplied with so many compound microscopes that only one person should have access to the same instrument during any term; it should have microtomes, reagents in abundance, with all needed apparatus for experiments in plant physiology and for photography. It should have duplicated volumes of needed reference-books all the time in the class-room, besides a generous library. It will not be complete without a museum of plant-products and numerous greenhouses for giving different varieties of temperature, light and moisture. Beyond question, it should have a botanic garden and arboretum, where growing plants could be studied, each in the soil and exposure best adapted to it. Of course, it should have a liberal, uniformly increasing and permanent endowment, not only because a properly equipped and conducted botanic garden in itself involves an immense outlay of money, but because the botanic department of a progressive university, if it is under efficient management, will develop in all directions just in proportion to the means at its disposal.

This is a broad and far-reaching scheme, and one which we can hardly hope to see realized in the immediate future, but it is, after all, the most hopeful direction in which we can look for genuine improvement in the arts of agriculture and horticulture. No surer foundation for substantial improvement in these arts can be laid than a broader and deeper knowledge of the sciences on which they rest; and certainly the science of plant-life is chief among these. We can hardly expect that the General Government, which has been so liberal with these colleges, will

add materially to their present endowment, and we know of no way in which public-spirited men can render a higher service to their country than by following the example of Mr. Shaw, who founded the botanical garden at St. Louis. Personal fame is not the primary object of liberal citizens of this class, but in no other way could a man rear a monument more creditable or more enduring than by multiplying the facilities for instruction and research in the science of botany in its broadest sense at some of our institutions of learning, where an efficient and progressive administration of the gift would be assured.

A Reclaimed Swamp.

TO make waste places attractive is one of the self-evident duties usually neglected by the average property-owner. Our road-sides are too often covered with weeds and rubbish, and well-kept ones are local to certain communities, where an orderly sentiment has been encouraged by some energetic resident, rather than general in even the oldest settled sections of the country. But if orderly road-sides are exceptional, still more rare must be the reclamation of waste places, such as swampy lands and sink-holes, so often seen near traveled highways. That such waste lands can be made attractive by well-directed private efforts may be learned by the picture of a reclaimed swamp, whose present beauty is owing to the labors of Mr. S. C. Nash, of Clifton, New Jersey. A few years since, as has already been told in GARDEN AND FOREST (vol. v., p. 310), this tract was a low-lying swamp stretching along the main road, and covered with an ugly mass of weeds and unsightly refuse. These have been cleared, the sloping banks graded and covered with soil to smother the strong-growing indigenous plants. The low-lying portions have been widened out into basins with informal edgings, which, as will be seen, have been planted with Irises, Wild Rice, Sedges and noble Grasses. The view (page 499) having been taken from a low level fails to convey an adequate idea of the size and character of the basins which are utilized for the cultivation of Nymphæas. The water in the middle distance—at the outlet—is separated from the more ornamental basins by a low dam, which is made necessary by an occasional backing up of river-water. This section, comprising several acres, has been cleared and planted with surplus Nymphæas, and in its plainer condition is a foil to the section in the middle and left of the picture. The middle basin of about an acre, and the narrower channels leading to it, are planted with a complete collection of hardy Nymphæas, some of which have made large masses. The continual flow of spring-water having proved rather cool for tender Nymphæas, these have been provided for in tanks made by sheet-piling. These tanks are marked in the picture, and their banks masked in reality by various aquatic plants and tropical ones, of which the Musas are the most prominent in the view. Mr. Nash has grown and flowered *Victoria regia* in one of these tanks this summer. The upper section of this park (not shown in the picture) is a cleared space divided by a small stream from a wooded lot, from which issues water which has been led through quiet pools, reflecting many a pleasant picture of sylvan beauty.

One more feature of this reclamation must be noticed. If the picture were continued to the right the distance would show a most charming wild garden in the best meaning of that well-abused term. The wild garden here is not a plantation for those weeds and gross-growing plants exiled from good gardens, but is a garden which is being gradually planted in a natural way with the best native plants hardy in this latitude. It is a pleasure to walk through a wild garden planted so much in character that one comes across an Orchid, an Iris or some dainty native plant, with very much the same feeling of discovery that one experiences in finding the plant in its native haunts. This seems to me the art which is nature in such gardening.

The picture on page 499 is a view of one section of the middle basin, and conveys an excellent idea of effective plantings at the edge of the water and a beautiful shoreline. It, at the same time, is a beautiful illustration of *Nelumbium speciosum*, showing its natural habit in all stages and its effectiveness in a clear pool with ample water space. Here may be seen the leaf floating at the surface of the water, as happens when growth is first made, and other leaves in all stages, from the tiny arrow-head-like coil to the broadly undulating, perennially interesting, fully expanded specimens. Even in the picture they show the various tones of light which render them so attractive. The rambling habit of the plant is well illustrated in the detached smaller groups, which are from creeping stolons of the main growth. Many illustrations of this Lotus have been published which are not true to nature; this picture, therefore, showing its true character must prove interesting.

Mr. Nash's garden, it will be seen, is bounded at the left by the public road, from which it is in full view and easy of access, so that, while it is a private garden, it is practically a public park, open to all, and an improvement which would be welcomed in any locality. Such an example as this seems worth imitation. There are many such spaces whose reclamation would furnish interesting occupation for those fond of nature, aside from the public benefit given.

A FINE consignment of Palms and Tree-ferns recently left Boston for Chicago, the plants being gifts to the Horticultural Department of the Fair, where, under the big dome of the fine building beside the lagoon, it was thought best to establish them before frost set in.

From the Harvard Botanical Garden went two specimens of *Livistonia Sinensis*, which are about twenty years old. For a number of years their growth was retarded by the use of small pots, but when they were planted out in the new Palm-house of the Botanic Garden they grew with surprising rapidity. Their height is now thirty-four feet to the top of the tallest leaf, while at the base of the stem they girth six feet, and the fan-shaped leaves, about fifty in number on each plant, are between five and six feet long. The third contribution of the Botanical Garden is a *Seaforthia elegans* about twenty-four feet in height, with a clean smooth stem up to half this height, and leaves about ten feet in length.

From his famous gardens at Wellesley, Mr. H. H. Hunnewell sent a fine Tree-fern—a *Dicksonia regalis*, with a stem about five feet high and thirty inches in circumference; a *Pandanus reflexus* eighteen feet in height, with fifty-five leaves, each about eight feet long; a *Cocos Bonnettii* eighteen feet high, with thirty fronds, which spread so widely that it will require a place more than fifty feet in diameter for its exhibition, and two specimens of *C. coronata*, each twenty-four feet tall. All these specimens, we are told, had been growing in Mr. Hunnewell's conservatory for at least twenty-five years.

The consignment was completed by three trees from the private greenhouse of Professor Sargent. These are a *Kentia Wendliana*, about ten years old, which was raised from the seed by Professor Sargent; a *Chamerops excelsa*, forty years or more of age, which is sixteen feet tall and spreads ten feet, and a *Phoenix reclinata*, nearly thirty years of age, which measures about fourteen feet in height and as much in spread.

Carefully packed, these admirable plants filled two cars, and as soon as they reached Chicago were to be set in place beneath the great roof, where they will have such a chance as never before to develop as rapidly as they choose. This chance will probably be particularly welcome to the two Bourbon Palms from the Botanic Garden, as, during last winter, they broke the glass above their heads several times, and when the weather became warm enough for a renewal of the glass to be needless, promptly grew six feet in the open air.

The Supposed Correlations of Quality in Fruits.

AT the Rochester meeting of the American Association for the Advancement of Science, Professor L. H. Bailey read a paper on this subject, the greater part of which we herewith reproduce :

High quality in fruits, by which we mean that combination of fine texture, tenderness and pronounced agreeable flavor which renders them fit for dessert, is supposed to exist at the expense of some other character. The best fruits are thought to be tender in tree, unproductive, to lack vigor, or to be small or dull in color. This notion is one of the dogmas of horticulture which has passed down from generation to generation unchallenged, and it is the parent of the common assumption that a first-rate market fruit is almost necessarily one that is indifferent or poor in quality. The correct understanding of this general belief lies at the foundation of all advance in horticulture, for if variation in quality is always correlated with variation in some other character, we should be able to breed directly for quality by means of simple selection, taking seeds, for instance, from the tenderest tree or the least productive, to secure the highest quality in fruit. But we must first determine if the law of Goethe and St. Hilaire, that the sum of activity in any plant is fixed, with variation occurring only within the limits, is true, or if we can force the plant beyond its original bounds, and increase the sum of its activities. We must determine if the independent variation of organs which Wallace has found to exist in nature, obtains also in the garden, or if, once inside the garden-fence, the plant assumes a law of development in parallelisms. It therefore becomes a philosophical question.

Now, there are about seven characters which are commonly held to be correlated with marked increase in quality, three of which belong to the fruit itself, and the remaining four to the plant as a whole. These are: Decrease in size or seed-production or loss of high color in the fruit, tenderness, lack of vigor, short life or unproductiveness in the tree.

There are two methods of discussing my subject, the statistical and the philosophical. Fortunately, statistics are at hand for our purpose. I have selected as the basis of my investigations the well-known fruit-catalogue of the Michigan Horticultural Society. This is almost wholly the labor of T. T. Lyon, whose discriminating judgment upon the merits of fruits is not excelled in this country. In this catalogue all the varieties are graded upon a decimal scale in three distinct categories—dessert, cooking and market. Each variety is also rated in size and color. Mr. Lyon's standard of excellence in quality for dessert is high, and only the very choicest varieties reach figures nine and ten. It therefore offers an opportunity for the selection of extreme types and the elimination of all such intermediate ones as would be likely to complicate and obscure the results. The catalogue is also extensive enough to afford a safe basis of estimate; it contains 219 varieties of Apples, seventeen of Blackberries, fifty-two of Cherries, sixteen of Currants and Gooseberries, forty-seven of Grapes, seventy of Peaches, sixty-three of Pears, thirty-four of Plums, thirty of Raspberries and sixty-one of Strawberries.

I have examined for comparison the records of the size and color of all those varieties which scale nine and ten for dessert. There are thirty-eight varieties of Apples graded nine and ten, of which only three are rated small, while seven are large and two are very large. Those rated as medium to small are two, and those medium to large are three. Of these thirty-eight entries, therefore, six, or less than one-sixth, would be called small apples, and thirteen, or over one-third, are large apples, the remaining ones being classed as medium or intermediate. In other words, there are over twice as many large apples as small ones of very high quality in this list; and there is every reason to believe that what is true of the 219 varieties here considered is also approximately true of all varieties in cultivation, for the list contains a very large proportion of the total number of varieties of high quality. Of the seven Blackberries rated nine and ten, five are large, one is medium and one is medium to small. Of the sixteen best Cherries, eight are large, two very large, one medium to large, and none of them are small. Of the three Currants, one is large and the others are medium, and the two Gooseberries are large or medium to large. Among the eight best Grapes, there are three large-bunch varieties and one small-bunch. Of twenty-one best Peaches, none are small, twelve, or over half, are large, two are very large, and one is medium to large. Among twenty-one best Pears, five, or nearly a quarter, are small, three are medium to small, while six are large and two are medium to large. In this instance, the numbers of large and

small are equal. In the six best Plums, but one is small. Of eight Raspberries, none are small, but four are large and two are very large. In the twenty-three best Strawberries, none are small, while six are large, and eleven, or nearly one-half, are very large.

There can be but one conclusion from these figures, and that is that quality is not associated with size of fruit. If the figures were to be interpreted as they stand, it would appear that increase in quality is usually associated with increase in size, but it must be remembered that small fruits are less likely to be propagated extensively than are large ones. It is only when small fruits possess some superlative merits, as in the case of the Early Joe Apple and the Seckel and Summer Doyenne Pears, that they are worth cultivating in competition with larger fruits. And thus it would be useless to attempt to draw any conclusions from the listed sizes of poor apples, for poor small apples are not often perpetuated. We need not resort to figures to show that increase in quality is not a necessary attendant of decrease in size. Every fruit-grower who stops to reason upon the question must recall the fact that "seedling" Apples are usually small and very poor in quality. The fallacy of associating size and flavor, as of other supposed parallelisms, arises from the fact that individual instances have been widened into generalizations. We wonder at the smallness of the Russets, the Early Joes, the Delawares, the Seckels and the Doyennes, but we forget the Fall Pippins, the Hubbardstons, the Spys, the Greenings, the Brightons, the Anjous and the Boscs. But if it is a fallacy to associate increase of quality and decrease of size, it is perhaps a greater one to associate high quality with low color. A study of the preceding tables shows that red is a very prominent character in all the fruits, and wholly green fruits, even among the apples, are rare.

In many varieties the seed production has decreased, and it has been held by some that there is a correlation between it and quality. The chief exponent of this hypothesis is Dr. E. Lewis Sturtevant, who outlined his views before the American Pomological Society at its last Boston meeting. He has made a fuller discussion of the subject in a recent paper, in which he asserts that "there seems to exist in fruits a correlation between seedlessness and quality, especially when that quality is expressed by the term tenderness of tissue. In fruits of fine quality, tenderness of the seed-coating often seems a marked characteristic, as in grapes, where the seeds of the improved varieties are distinctly softer and more brittle than in those of the wild species; as in peaches and plums, where the tendency of a split stone is often noticeable in fruit of varieties of high quality." I have made no studies concerning the strength or thickness of seed-walls in cultivated fruits, but I do not doubt that there is a general tendency toward fragility. But I cannot look upon this tendency, if it exists, as in any way related to quality. It is undoubtedly due to constant selection for small-seeded fruits. Concerning the relations of seed-production to amelioration, I have made some careful studies. I have found, as a rule, that the cultivated varieties of Apples contain more seeds than the wild European Crabs. Forty specimens of fruit of these Crab-seedlings contained a total of 256 seeds, or an average of six and two-fifths seeds to the fruit. Forty Northern Spy apples yielded four hundred and eighty-one seeds, or an average of over twelve to the fruit. Normally, the apple contains five carpels, and each carpel contains two seeds, but some of these Spys had fifteen seeds and one had eighteen. And yet the Northern Spy ranks ten in Mr. Lyon's dessert scale. I had all the seeds counted in a pound of each of thirty samples of tomatoes, representing twenty-six varieties of very different degrees of amelioration. The lowest comparative seed-production was in the Cherry Tomato, which is very near the wild type. There was found to be a general, but uncertain, increase in seed-production as the variety departs from the Cherry Tomato, but this increase bears no relation whatever to the extent of departure. Now and then an orchard-fruit appears which is almost or wholly seedless, but it is not necessarily of high quality. So-called coreless apples and pears occasionally appear, but none of them have ever had sufficient merit to warrant their extensive propagation. Barren mentions two no-core apples, one of which is recommended only for kitchen use, and the other is characterized as worthless. I do not wish to discourage the sowing of seeds from few-seeded fruits, for the practice is probably a means toward still further eliminating seeds, but I see no reason to expect any unusual increase of quality from this source. Seed-production appears to me to be subject to the same laws of variation as other attributes of plants, and it appears independently of other characters, in the same manner as size and color.

In comparing the habit and vitality of the tree in the best varieties with the poorer ones, it must be borne in mind that a tender, or weak-growing, or unproductive tree which bears poor fruit is unfit for cultivation, and such varieties do not often appear in the fruit lists. But, on the other hand, such trees are often cultivated because of some superior quality of the fruit. So it happens that the poorest trees and least productive ones described in our manuals are apt to produce fruits of the highest quality, and growers are apt to enlarge this circumstance into a generalization. But, the fact that Winter Nelis is a poor grower, that the Delaware Vine is slender and particularly liable to mildew, and that the Newtown Pippin is unreliable, is many times overbalanced by the vigorous growth and productiveness of Anjou, Catawba and Northern Spy and many others. In fact, a study of the dessert fruits in this catalogue will show that over eighty per cent. are hardy, vigorous and productive. In regard to the notion that the best fruits are usually short-lived, I have only to say that there are positively no facts to support it.

It is also generally believed that market fruits are either poor or indifferent in quality, but here again facts do not warrant the belief. It must be remembered that many of the best dessert fruits are cultivated solely for the sake of the one character of high quality, while the best market fruits are cultivated for a variety of features, as size and color of fruit, vigor, hardness and productiveness of the tree, and quality is usually not considered. Market fruits and dessert fruits are not, therefore, strictly comparable. But if there are any good market fruits which are at the same time good dessert fruits, we shall be obliged to admit that market qualities and table qualities are not incompatible. Of the 219 varieties of apples catalogued by Mr. Lyon, nineteen are rated nine and ten for market. Of these, six, or about one-third, also rate nine and ten for the dessert, as follows: Golden Russet, Hubbardston, Jonathan, Northern Spy, Peck's Pleasant and Rhode Island Greening. Of these six, four rate the same for both table and market and two rank one higher for market than for table. Moreover, there are four other varieties which rank as high as eight in quality, which is two points higher than the Baldwin. Of the ten best market blackberries, four are included in the select dessert lot. Fourteen cherries rate nine and ten for market, and just half of them are in the select list. Of the eight best market currants, however, only one is rated high for dessert, but the currant has not been developed in the direction of high quality. Of the four market gooseberries, two are in the other list. Mr. Lyon admits but six market grapes, of which one is a superior table fruit. Of the market peaches, nearly one-fourth are dessert fruits. One-fourth of the market pears rank highest for dessert, while one-third of the remainder rank as high as eight, which is the rating of the Bartlett and Sheldon. One-seventh of the best market plums are best for dessert, and nearly a third rank eight. Of the dozen best market raspberries, one-fourth are best table sorts, while half of them rank eight. Over a third of the market strawberries are dessert varieties. All these facts show conclusively that high quality is not incompatible with that combination of characters which makes a fruit good for marketing, and they show that a very large proportion of our market fruits actually are dessert fruits. And if we take the average quality of all the fruits ranking nine and ten for market we find it to stand uniformly at seven or above for dessert, or higher than medium quality. Thus the average table rating of all the high market apples is 7.1, or over one point higher than the Baldwin. The average of the market blackberries is 8.5. This instance is particularly interesting, because the blackberry is probably the fruit oftenest cited as decreasing in quality in proportion as it is increased in size. Cherries average 7.3, and grapes 7.8. Peaches average 7.6, which is higher than the rating of Late Crawford, Barnard and other standard sorts. Market pears stand at 7.7, or higher than Angouleme, Flemish Beauty, Superfine and Louise Bonne. Plums average seven. Raspberries give an average of 7.8. Strawberries are eight, which is the rating of Kentucky, Miner, Ohio, Sharpless and Charles Downing. It is impossible to construe these facts to mean anything else than that all desirable characters of fruits may progress simultaneously.

In this connection we should discuss the popular notion that the berry fruits decrease in quality when they are brought into cultivation, because the decrease is supposed to be due to increase of size and vigor. Most people think of the wild strawberries and blackberries of youthful rambles as possessing unusual sweetness and aroma; and I do not doubt that it is true, even allowing for the exaggeration of retrospect, that wild berries are sweeter than those which we commonly obtain from the garden. But I know of no reason for believing that

wild fruits are actually sweeter than tame ones. I am convinced that it is mostly a question of ripeness. To be sure, there may be cultivated varieties inferior in quality to some wild berries, but, as a rule, I do not believe that cultivation has had the effect of decreasing quality. I have given particular attention to this question this year with blackberries, which are very generally considered to have lost sweetness by transfer to the garden. Among garden varieties I have studied Agawam, Early Cluster, Early Harvest, Ancient Briton, Snyder and Stone, and two of these are rated as low as eight for dessert by Mr. Lyon, while the poorest varieties go only as low as seven. In the study of wild berries, I visited a region which I had known in boyhood, and which I have always remembered because of its great and luscious blackberries. But the comparison was greatly in favor of the tame berries if they are allowed to remain upon the bushes until ripe. In the wild patches we practice an unconscious choice, and pick only those berries which please us. We pick the ripest and the best. It is noticeable, also, that we pick the largest, and base our judgment upon them, while we should find the best quality in the smallest berries if our assumed logic is sound. Cultivated berries, when marketed, are necessarily picked before they are ripe, and they never reach their full quality. And even when picked for table use, blackness in the blackberry and redness in the strawberry are usually considered as measures of ripeness. But the true measure of ripeness is softness. A well-grown fully ripe blackberry, which falls into the hand when the cluster is shaken, possesses a tenderness, juiciness and sweetness which I have rarely found in a wild berry. And the same is true, in my experience, of strawberries and raspberries.

But we do not need to rely upon individual tastes, for all chemical examinations which I have been able to find show that sweetness increases with the increase or intensification of culture. This would seem to be almost necessarily the case, because the ultimate aim of cultivation is to supply more food to the plant, and this food in fruits is largely potash, which bears a definite ratio to sugar. Dr. Stone reports a series of interesting experiments in this direction at the Massachusetts Agricultural College. "A wild specimen of *Vitis Labrusca* (our common Wild Grape) was torn apart at its root; one-half was left in its natural condition, the other transplanted to cultivated ground and treated with nitrate of potash and bone superphosphate. At the end of three years fruit from the cultivated vine contained twelve per cent. more potash and twenty per cent. more sugar than that from the wild one." Analysis of wild and cultivated strawberries showed a great increase in potash in the cultivated variety. "But the change was not confined to the mineral elements alone, for the same analysis showed that the proportion of sugar to acid in the wild species is as two to one, while in the cultivated varieties it is increased to six to one or more." Dr. Stone further declares that "potash fertilizers have decidedly improved the desirable qualities of fruits. Wherever the percentage of this element has been raised, the change is accompanied by an increase of sugar and decrease of acid." Dr. Stone has made a subsequent examination of the chemical composition of strawberries at the Tennessee experiment station, and he finds that, "in the varieties examined, the proportion of acid to sugar was 1 to 3.5. For the wild strawberry, the only references available, and these very meagre, show a corresponding proportion of 1 to 2. This indicates that a change for the better has been made, but it is far from probable that the limit has been reached." Fresenius gives the sugar in cultivated strawberries as 7.5 per cent., and the free acid as 1.13, and in the wild berries as 3.2 and 1.6 per cent. respectively. Cultivated raspberries, according to the same authority, contain 4.7 per cent. of sugar and 1.3 per cent. of acid, while wild ones contain 3.5 per cent. of sugar and 1.9 of acid. Parsons finds that sugar increases rapidly in oranges as they depart from the wild type, although free acids do not show a corresponding decrease. Thus the wild bitter-sweet of Florida contains .84 of cane-sugar and 5.71 of glucose; the sour, .97 cane-sugar and 3.36 glucose; the common oranges, 4.38 and 4.60 respectively; russets, 4.51 and 7.29; mandarin, 8.07 and 4.77. The figures and experiences uniformly show that amelioration in other qualities is accompanied by an increased sweetness; and every one who has tested seedling or wildling fruits can bear testimony to the same fact.

But if all statistics show that high quality does not proceed at the expense of other characters, practical experience in the origination of fruits shows it as well. As a matter of fact, seeds of small or low-color fruits, or from tender or unproductive varieties, do not give a larger proportion of varieties of high quality than seeds from large, highly colored and vigorous kinds. And it is here worthy of remark that while most

pomologists hold to the correlation of quality with decrease of other characters, they at the same time uniformly recommend that in producing new varieties only seeds from the largest, finest and hardiest varieties should be used.

It is evident from our discussion that quality and other characters of cultivated fruits appear independently of each other; that there is no true correlation between these characters. There is a general increase in all characters as amelioration progresses—at least in all characters which are particularly sought by horticulturists; and this fact must ever remain the chief inspiration to man in his efforts to ameliorate plants.

New or Little-known Plants.

New Orchids.

CYMBIDIUM HUMBLOTTII, Rolfe.—A fine Madagascar species, the second now known from that island, with a large branching panicle of green and black flowers, which resemble those of *Cœlogyne pandurata*. A plant was exhibited at a meeting of the Royal Horticultural Society on June 7th last by C. Ingram, Esq., of Godalming, and was awarded a botanical certificate. Dried specimens were sent home by Monsieur Humblot, and it is highly probable that the living one came from the same source.—*Gardeners' Chronicle*, July 2d, p. 8.

ONCIDIUM ROLFEANUM, Sander.—A New Granadan species allied to *O. Kienastianum*, Rchb. f., and *O. trilingue*, Lindl. It was introduced by Messrs. F. Sander & Co., of St. Albans, who exhibited it at the last show held by the Royal Horticultural Society in the Inner Temple Gardens, when it was awarded a botanical certificate.—*Gardeners' Chronicle*, July 9th, p. 34.

PHALÆNOPSIS × *ARTEMIS*, Hort.—A pretty hybrid raised from *P. grandiflora* crossed with the pollen of *P. rosea*. It bears some resemblance to *P. × intermedia*. It was exhibited by Messrs. James Veitch & Sons, of Chelsea, at a meeting of the Royal Horticultural Society on July 12th last, and received an award of merit.—*Gardeners' Chronicle*, July 16th, p. 75.

DENDROBIUM CHRYSOCEPHALUM, Kranzlin.—A species belonging to the section *Pedilonum*, with golden-yellow flowers very similar to those of *D. viridiroseum*, Rchb. f., in shape. It was introduced by Messrs. F. Sander & Co., of St. Albans, and flowered in the collection of Prince Lichtenstein, of Moravia.—*Gardeners' Chronicle*, July 30th, p. 122.

MASDEVALLIA HARRYANA GRAVESIÆ, Rolfe.—A pure white variety of this handsome species, and exceedingly rare. It was introduced by Mr. F. Mau, of Orange, New Jersey, and flowered in the collection of Henry Graves, Esq., of the same place.—*Gardeners' Chronicle*, July 30th, pp. 122, 131, fig. 21.

CYPRIPEDIUM × *BRYANI*, Hort.—A very handsome hybrid raised from *C. Philippinense* crossed with the pollen of *C. Argus*, in the collection of N. C. Cookson, Esq., of Wylamontyne. It received an award of merit from the Royal Horticultural Society on July 26th last.—*Gardeners' Chronicle*, July 30th, p. 138.

London Letter.

NEW ORCHIDS AT THE SALE-ROOMS.—There is an inundation of new or so-called new Orchids in the English market now, chiefly in the London auction-rooms. Collectors display more energy than ever in sending home large quantities of plants, with tempting descriptions of the beauties of their finds and graphic accounts of the terrors and trials they had to undergo to procure them. The old style was quite different. The collector was a secret worker, his movements were unknown to all save his employer, and if he suffered much there was little said about it. Now every importation has a history, an attractive one, and "our collector" tells of the cannibals, venomous serpents, ferocious animals, treacherous servants, etc., etc.,

which he had to encounter in his search for the plants which are now offered at any price you like, only please note there are no more because "our collector" says he has gathered every one or an earthquake came and swallowed all that he left. The perils of the "Orchid hunter" have already been the subject of a serial story in an English weekly. Meanwhile there is no difficulty in getting men to go on these perilous errands, and as a rule they thrive wonderfully well, spite of serpents and cannibals.

This "romancing" does no harm, indeed it is often interesting. One wonders how far the collector will go in his desire to spin a yarn, which is meant, we suppose, to inspire rival collectors with fear. Mr. Grant Allen recommends any one who has thoughts of taking up literature as a profession to buy a broom and sweep crossings instead. The plant collector now talks in the same strain. Meanwhile thousands of pounds are spent on Orchids now where tens were spent before. There is certainly no sign of abatement in the Orchid fever.

CYCADS.—The collection of Cycads at Kew is the richest known. It comprises many very large specimens, some of which frequently produce very fine cones. There are more cones than usual just now, the following being specially noteworthy: *Dioon pectinatum*, a newish species, previously called *D. spinulosum*. It differs from *D. edule* in having broader, thicker pinnæ, toothed near the apex. The cone, a male, is one and a half feet long by four inches in diameter. *D. edule* is also in fruit, the cone, a female in this case, being as large as a man's head. *Encephalartos villosus* has two beautiful cones rising from the centre of a grand rosette of arched leaves eight feet long. Each cone is one and a half feet long, half a foot in diameter, and built up of regular angular fleshy scales colored soft orange, not unlike a huge pine-apple. When the scales open and partly show the rich scarlet seeds the effect is particularly attractive. *E. Altensteinii*, the giant of the genus, has a head of leaves fifteen feet through. It is a grand plant for a large house, grand as any plant I know; moreover it is as good-natured as a *Dicksonia*. There are several very large specimens of it, one or other of which is always in cone. There are a pair of male cones eighteen inches long on one of them now. *Macrozamia spiralis* has a short conical stem two feet in diameter and long flaccid leaves of a rich green color. The one in cone now has no less than six fine male cones, each nine inches long and colored pale greenish yellow. There is not much difference in habit between this and *M. Fraseri* and *M. Moorei*. Another of the same stamp, named *M. Dyeri*, has recently been added to the Kew collection.

These large sturdy Cycads are most valuable plants for furnishing large houses. They are always good to look at, magnificent in every sense, and they are, as a rule, among the easiest of plants to cultivate. Large stems of them may be sent long distances without suffering, most of the big specimens at Kew having been obtained from Australia or Africa by means of stems dug up and sent without any soil in dry boxes. Some years ago a large stem, ten feet long, of *M. Moorei*, which had been sent from Australia by Sir F. von Mueller, showed signs of decay at the base of the stem. To save it the stem was cut in two and the upper half planted as a cutting. It rooted in time, and is now a fine healthy specimen. The South African Cycads, such as *Encephalartos villosus*, *E. Caffer* and *E. Altensteinii*, ought to thrive in the open air in such states as California.

STEVENSONIA GRANDIFOLIA.—This is a Palm of more than ordinary interest. It is a native of the Seychelle Islands, where it is said to be common, but, as is the case with several other genera found in those islands, it does not occur in any other part of the world. It is monotypic. It grows to a height of fifty feet, and has a slender, annulated, unarmed, dark brown stem, the upper part of which is clothed with the hard sheathing bases of the leaves. Young plants have numerous black spines an inch long on the leaf-stalks, but as the plant increases in size these

spines gradually disappear. The leaves are large, cuneate-obovate, bifid at the apex, with marginal divisions or segments, which are notched at the tip. The blade is rich green, margined with orange and blotched with reddish brown. In very young plants the orange-colored petiole, midrib margin and blotches of the leaves are really ornamental.

For the discovery of this Palm we are indebted to Mr. Duncan, once a young gardener at Kew and afterward curator of the botanical garden at Mauritius. He found the Palm in Round Island in 1855, and sent three seedlings of it to Kew. He named it in compliment to the Governor of Mauritius, who did much to assist Duncan in his botanical work. One of the three seedlings disappeared from Kew in 1857 and reappeared in a Continental garden in 1857, a circumstance which led Wendland to name the

the Seychelles and the decidedly beautiful character of the young plants. Like all, or nearly all, the Palms from the Seychelles it requires a tropical stove temperature and plenty of moisture all the year round. It is peculiar in being so very spiny when small, and spineless when large; it is also remarkable in the rusty red blotches on its leaves, which might easily be mistaken for the marks produced by insects; indeed, I have heard of a plant being condemned by the judges at a flower-show on account of these "unhealthy" spots.

Other Palms, which are endemic in the Seychelles and monotypic, are *Verschaffeltia*, *Roscheria*, *Nephrosperma* *Deckenia* and *Lodoicea*, the double Cocoa-nut. These are all in cultivation at Kew and in other gardens where Palms are in favor.

plant *Phœnicophorium*, or Stolen Palm, a name by which it is still known. Another of the seedlings died, but the third still remains, and is now one of the handsomest specimens in the Palm-house. It is thirty feet high, with a stem nine inches in diameter and eleven fine leaves, each with a curved, channeled petiole four feet long, and a broad entire blade seven and a half feet long by five feet wide. This plant is now flowering for the first time. The inflorescence is at first enclosed in a club-shaped woody spathe three and a half feet long, which splits longitudinally and falls off, exposing a branched panicle a yard long clothed with bright yellow flowers. As the plant is monœcious, it will probably produce a crop of fruits. A figure of it has been prepared for the *Botanical Magazine*.

Stevensonia, or *Phœnicophorium*, is rare in cultivation, notwithstanding that the seeds are easily procured from

Cultural Department.

Grafting Grapes.

IN the vineyard districts of New York, the matter of Grape-grafting is becoming an important one for the growers. Many vineyards which are now in bearing consist of varieties which, when planted, promised abundant returns. But all the promise was not fulfilled to the satisfaction of the grower. There are many men who would be glad if their vineyards were bearing other varieties of grapes than those now produced, and the question whether these vines could be grafted with the desired varieties has been discussed with considerable earnestness. The Cornell Experiment Station has undertaken to throw some light upon the matter, and during the past spring several methods of grafting the Grape were tried. Some of the methods which give the best results in Europe were followed as well as some which are not in common use.

Although the season's work shows some marked failures, still the lines in which future work should be carried on are quite clearly defined.

About twenty vines of the Red Wyoming Grape were used for each kind of graft, and cions of the Niagara were inserted. With one exception, the cions were about ten inches long and

ordinary cleft graft. The stock was cut off about three inches above the ground, and after the cions were inserted all cut surfaces were covered with grafting wax. None of the cions lived.

(2) The same method was again adopted, but the wounded portions were protected with a thick layer of clay and cow-

Fig. 85.—The Sacred Lotus in a Reclaimed Swamp.—See page 494.

carried two or three buds; the stocks were six years old. The work was done April 4th, the weather at the time being quite warm and the sap was flowing freely. The following is a brief outline of the various methods used and the results reached:

(1) In this case the cions were inserted in the stock by the

manure, mixed in equal proportions. This dressing is said to be of much value in Grape-grafting, but in this case its virtues were not manifest. All the cions died.

(3) This method is called by Baltet side-grafting with an oblique cleft. A slanting cut is made downward on the side of the stem, at any desired height, but the knife is drawn

down much further on the side toward the handle. Into this oblique cut a wedge-shaped cion is inserted and tightly bound. No wax was applied. None of the cions grew.

(4) The operation was performed as described in 1, but the stock was cut below the surface of the ground and just above the highest roots. All cut surfaces were covered with common grafting wax, after which the earth which had been removed was replaced. This method gave better results, for about sixty-one per cent. of the cions made a fine growth.

(5) The work was done as in 4, but no wax was used. Sixty-eight per cent. lived.

(6) The stock was cut below the ground, as in 4. Two longitudinal V-shaped cuts, about one and one-half inches long, were made upon opposite sides of the stubs, and the cions were cut so that they fitted into these grooves as neatly as possible. They were then securely tied, but no wax was applied. In the fall, eighty-six per cent. of the stubs carried vigorous canes.

(7) The stock was prepared as in 4. Upon one side of the stub the bark was cut away, so as to leave a flat, smooth surface about two inches long and half an inch wide. The cions were cut about eighteen inches long, and eight or ten inches from their upper extremities a cut similar to that in the stock was made, only it was not so wide. The two cut surfaces were pressed together and firmly tied, the lower extremities of the cuttings being buried in the soil. This method gave the best results, for fully ninety-three per cent. of the stubs (or the cuttings) carried canes in the fall. The growth was much stronger than that made by ordinary cuttings, for in some cases it aggregated fully seventy-five feet.

From these experiments it would appear that the best place to graft Vines is under ground; whether wax or any covering other than earth is beneficial still remains to be determined. In these experiments the wax did not seem to do very much good. If the cions were inserted by the cleft graft and almost buried with earth, excellent results would probably be obtained, and this method can be most safely recommended. Methods 6 and 7 may even be better, but the operations are more tedious.

The French have not contented themselves with using only mature wood in grafting the Grape; they have given much attention to this subject, and some advise the use of soft wood. The following extract from an article by René Salomon, which appeared in *Vigne Americaine*, will give a fair idea of the manner in which this work is done:

"Herbaceous grafting is very easily performed; in half an hour a novice can become so skillful in the operation that from eighty to ninety per cent. of the grafts will be successful, provided: (1) That the vine is in its most active period of growth; (2) that the weather is sufficiently warm (at least sixty-five degrees, Fahrenheit); (3) that the shoots used are sufficiently strong, and neither too hard nor too soft; they should still be flexible, yet the centre should be free from pith; (4) that the cions are placed beneath the fourth bud from the extremity of the shoot; (5) that the cions contain at most only two buds. After being cut they should be kept a few days in damp fresh grass, and they are then ready for use. In fact, the most essential condition for success is the more or less herbaceous condition of the cion and the stock."

The splice-graft is the method recommended by Salomon. He advises making the oblique cut through the centre of the nodes, both in the cion and in the stock. The cuts are made as nearly the same as possible, and the two pieces are then firmly tied together with a rubber band, for this is preferable to raphia, on account of its elasticity. After the operation the graft is protected from the sun and rain for about ten days, by simply rolling a grape-leaf about the place of union. In four weeks the rubber may be removed, for at that time from two to three inches of growth should have been made by the cion.

The Herbaceous Garden.

AS yet, although it is almost mid-October, there has been no frost to cause serious injury to outdoor vegetation. The Golden-rods and native Asters are still quite gay with flowers, and some of the other native plants are equally effective, although they are not so common or well known. The Boltonias, for instance, are free-growing plants of graceful habit, flowering profusely in August, September and October. They resemble the Asters closely, but they are of a more vigorous character, with large, smooth, lanceolate, pale green leaves. *Boltonia glastifolia*, said to be a form of *B. asteroides*, attains to a height of about six feet, and it is the first to bloom. The heads are about an inch and a quarter in diameter, the

ray florets being either pure white or of pale purple color, and those of the disk yellowish. *B. asteroides* flowers much later, and is now a fine mass of bloom. This, indeed, from the gardener's point of view, is the only material difference between it and *B. glastifolia*. The flowers of *B. latisquama* are to be seen side by side with those of *B. asteroides*, but this plant is only about four feet high, and it has smaller and narrower leaves than the latter. The heads, however, are much larger, being somewhat over two inches across, and the rays are bright purple. These three plants are perhaps the best of the genus for garden purposes. They grow well in ordinary soil, and are easily propagated from seeds or by division of the clumps in spring.

The Vernonias, commonly called Iron-weeds, are conspicuous for their dense cymes of dark purple heads. The flowers are perfect, and thus the individual heads have the appearance of double Daisies. *Vernonia altissima* is about eight feet high, leaves oblong-lanceolate, serrate, cymes very dense, and the flowers are at their best in August and September, the heads measuring almost two inches across. *V. noveboracensis* is very much like the last-named species. The leaves, however, are a trifle narrower, their serratures less prominent; the heads smaller, of lighter color, and developed in September, lasting into October, and the cymes are loose. *V. arkansana* blooms at the same time as *V. noveboracensis*; the heads and cymes are likewise similar, but the leaves are linear-lanceolate and denticulate. Vernonias and Boltonias make satisfactory progress under the same treatment, and they are propagated under the same methods. They look well in shrubbery plantations, and the flowers are admirable for cutting.

Each succeeding autumn adds to the popularity of the double-flowered varieties, *Plenus* and *Soliel d'Or*, of *Helianthus multiflorus*. They are as useful as *Chrysanthemum* or Dahlias, with the advantages over those plants of perfect hardiness and a rigidity of the flower-stems, which would be a vast improvement to the latter. They are about four feet in height, and the growth is free and compact. There are few better decorative plants, as they bloom freely from early autumn until cut down by severe frost. The flowers have no superior for cutting purposes, and they are more valuable because they will last two weeks in perfect form and color if cut soon after full development and given proper attention in the matter of water. The florets of *Soliel d'Or* are all large, but in *Plenus* those of the outer circle are more conspicuous than those of the centre. I prefer the more uniform structure of the flowers of the first-named, but both plants are eminently desirable. They are well adapted for town gardens, growing and flowering freely in almost any soil or situation, and they are readily increased by division. It should not be forgotten, in speaking of varieties of *H. multiflorus*, that *multiflorus* itself is merely a garden name for a form of our native *H. decapetalus*.

Roses.

APPARENTLY the most interesting among the newer Roses at the present time is *Madame Caroline Testout*. Many of the large trade-growers have already spoken in praise of this hybrid Tea, and the supposition now is that the new-comer will usurp the leading position among pink Roses so long held by *La France*. The flowers of *Madame Testout* are very large, and of a specially pleasing shade of pink; this color extends to the outer petals also, a quality not found in *La France*. As far as known at present, it is a strong-growing variety, producing fine foliage. As a rule, the buds are solitary, this also being a point in its favor, as disbudding is thus made unnecessary. As an indication of the anticipated popularity of this Rose, it is stated that a single selling-agent has secured control of a stock of 20,000 young plants for distribution next spring.

Another new Rose to be distributed next spring is the pink sport from *American Beauty* that originated with Mr. John Burton, of Philadelphia. This certainly seems to be an improvement on its parent, being equal in size and fragrance, and of a beautiful shade of pink, the color far superior to the dull hue so often seen in *American Beauty*, and especially after this Rose has been cut for a day. The sport retains its brightness for quite a length of time after being cut, and will undoubtedly prove a more satisfactory flower for the retail florists to handle. In token of his confidence in the good qualities of the Rose in question, Mr. Burton proposes to distribute the flowers in the regular course of trade this winter, thus allowing those interested a good opportunity to examine and compare the new Rose with its parent and other varieties

before purchasing plants in the spring. It may also be noted that as yet this sport has not been named, so that it cannot be more definitely spoken of than "Burton's sport from American Beauty."

Among indoor Roses in general this is one of the critical periods of the year, from the extreme liability of some varieties to contract mildew. Proper attention to watering, ventilation and heating, with applications of sulphur, removes this trouble readily. Probably the best method of applying the sulphur is by means of a bellows, after which the house should remain closed for a time in order to allow the fumes to operate on the fungus, keeping in mind the fact that if the temperature is allowed to run up above ninety degrees there is much risk of injuring the Roses.

The night temperature of a rose-house is rather difficult to regulate at this season without very careful firing. Fifty-eight to sixty degrees is the most satisfactory temperature for a majority of the varieties in general use, while special varieties may need either higher or lower than this average.

Difficulty is usually experienced in successfully growing a considerable number of different varieties in one house, but I recently saw a house in which were Papa Gontier, Catherine Mermet, Bride, Niphotos, Madame Hoste, Perle des Jardins, W. F. Bennett, Souvenir of Wootton, Madame Cusin and Madame de Watteville, and the grower informed me that the only varieties he had any trouble with were Bennett and Wootton; at the time I saw them even these were in nice condition.

The method of staking Roses, to which reference has several times been made in GARDEN AND FOREST, continues to grow in favor—that is, the plan of using galvanized steel wire rods in place of wooden stakes. These are kept upright by securing them at the top to a longitudinal wire attached to the roof of the house. The galvanized steel wire is very durable, does not require any painting, and forms the neatest possible support for the plants. It has in addition the merit of cleanliness, for it does not harbor vermin, as is frequently the case with wooden stakes. The canes that have frequently been used for this purpose form admirable hiding-places for the Snout-beetle (*Aramigus Fullerii*), and this pest is not slow in discovering any such cover. Fumigating or vaporizing with tobacco extract will be found necessary from time to time, vaporizing being the better method when properly applied, and less liable to injure the color of the flowers; but even this will affect the color if given too freely.

Holmesburg, Pa.

W. H. Taplin.

Lilies in Autumn.

MANY of the more valuable horticultural experiences are the results of accident, and not infrequently a little misfortune as well. Last spring one of our seedsmen had a number of cases of assorted Lilies left over from spring sales. After their journey from Japan in November of the previous year, and having been kept perfectly dry until the middle of May, the prospect of flowers from these bulbs was poor indeed. In hopes of saving something out of them, we planted the lot about May 20th. To our surprise, nearly all of them came up and made a vigorous struggle for life. The result was that this morning (October 10th) we have gathered from a bed of *L. Tigrinum splendens* as fine spikes as ever were cut in July. The plants of *L. speciosum* did nearly as well, but their flowers were over last week, excepting *L. speciosum Præcox*, which are in bloom, although the flowers are considerably damaged by the storm. *L. longiflorum* bloomed well, but were all gone a month ago. The plants of *L. auratum* behaved as they always do; some came up quickly, and flowered in August, and there have been flowers in the row every day since, while some are just coming up. These we shall pot for the greenhouse if there are enough to make it pay.

This experience has taught us that the season of Lilies can be kept up until after a hard frost with but little trouble, and add greatly to the display of autumn flowers. From the show these Tiger-lilies are making, it is evident they should not be allowed to bloom at any other season, as their deep, rich orange-crimson flowers are now in harmony with all their surroundings. For autumn flowers the bulbs should be taken up in November, packed away in dry sand or sphagnum-moss, and stored in some dry cool place until about May 15th. The low price of the bulbs of the *L. tigrinum* should make them popular autumn flowers, when they can be had with so little trouble and expense.

Floral Park, N. Y.

C. L. Allen.

Anthracnose of the Pear.—There is a considerable decay of the maturing pears due to an anthracnose. This rot of the

fruit is quite different from any other of the decays met with under similar conditions, and seems to have escaped identification. The fruit may be attacked at only one place, which spot soon turns brown and becomes sunken, as if it had been pressed upon with the end of the thumb. A little later the surface of the sunken place becomes covered with dark pimples, which are broad, instead of sharp-pointed, and finally become almost black. These pimples are the places where the spores are produced in great numbers upon the tips of projecting threads. The darkness of the pimples is due to the multitude of small black bristles which project in all directions from the centre of the mass of spore-bearing tips. Each pimple, in other words, is like a minute chestnut-bur, with microscopic spores borne between the spines.

A similar disease has been common upon the tomato during the season now closing. This trouble of the pear may be met with in the market, where it causes ruin to a fruit in a few days. Pears left upon the ground also exhibit the same, and become a means of propagating the anthracnose.

Correspondence.

The Future of the Fair-grounds.

To the Editor of GARDEN AND FOREST:

Sir,—What will eventually be the fate of the World's Fair-grounds at Chicago? All the buildings, except, possibly, one, will, of course, be removed; but a great deal of labor and of art has been bestowed upon the site as such, and how much of this will prove to have been expended for a temporary purpose only?

The northerly portion of the grounds had been laid out as a park before the Fair was proposed. This portion has necessarily been somewhat altered, but can easily be restored to a condition equal, or superior, to its former one. If Mr. Atwood's beautiful Art Gallery is preserved, as its fire-proof walls will permit, necessitating only the substitution of marble or terra-cotta for the present external covering of "staff," it will be a priceless addition to this part of Jackson Park. Moreover, this park is intimately connected with the new lagoon and its charmingly planted island, where the Japanese temple and garden will be permanently maintained; and it will not be difficult to transform the areas around the lagoon, now covered by great buildings, into harmony with its shores and with the regions further to the north.

But beyond the lagoon to the southward the grounds have been disposed in a very different way. Here the scheme is a formal one, and verdure does not enter into it at all. Here there is not only the fine, wide, curving esplanade along the lake-side, but the great rectangular basin, running in at right angles to the lake-shore, and branching out in front of the plaza into straight wide canals. At present the effect of the grounds, as a whole, is as harmonious as it is magnificent, terraces like those which border the basin and canals being carried for a space along the sides of the lagoon, where one of the canals debouches, thus intimately uniting, in a way which satisfies both the mind and the eye, the naturalistic and the formal portions of the great design.

But what is to be done with the formal portions after the Fair is over? Must the basin and canals be destroyed, and, if not, how can they be fitted into any artistic gardening scheme? An interesting answer to this question was recently given by a writer in the *Boston Herald*. "On the terraces which border the basin and canals," he says, "and on the wide level expanses left by the removal of the buildings . . . it would be possible to lay out a formal garden on a great scale, elaborate in design and with rich and brilliant effects in the harmoniously blending and contrasting colors presented by extensive flower-beds and formal shrubberies, studied as carefully with reference to coloristic impression as any woven or embroidered fabric in its conception. Such a treatment of that portion of Jackson Park would be a revelation in the field of formal gardening, and its success, which could not fail to be great, would go far toward creating a distaste for the atrociously bad art of so much of the prevalent methods in flower-bedding effects, repellant in both their awkwardness of design and their discordant colorings."

This interesting suggestion would, we think, offer an ideal solution of the problem but for one important fact. There is another name for formal gardening; it is also called architectural gardening, and in this name we find a hint of the obstacle which lies in the way of the easy realization of the proposed scheme. An architectural garden implies the presence of a work of architecture. A formal garden is the

natural accompaniment, extension and, so to speak, repetition of the straight lines and symmetrical masses of a building. It may be only a few rods square, or it may be as vast as the park at Versailles. But, whatever its size, it cannot look well—because it cannot look right and sensible—unless its formality is explained and justified by the presence of some structure with which it is intimately connected. As the basins and canals of the World's Fair are to-day, they are eminently beautiful because eminently right. The eye understands at once that they were planned as a means of approach to the magnificent structures which stand around them, and with which their own magnificence, in size and adornment, is in perfect keeping. But destroy the buildings and they would lose their purpose. They are not features which ought to exist by themselves, and they would not exist for the garden, should it be established; the garden would evidently exist for them. They would have no adequate purpose, and, lacking this, they would lose their artistic value and charm. If the great peristyle at the lake-shore end of the basin could be preserved with its flanking buildings, if a large but low structure for some public use could replace the Administration Building, and if a smaller structure could be placed at the southerly end of the canal, which the entrance to the stock-yards now finishes so finely, then indeed the treatment of the remainder of the grounds might be carried out as the writer in the *Herald* suggests, with a good prospect of producing the finest formal garden in the world. The finest, that is, in which avenues of trees do not play a conspicuous part, for such avenues ought not to be attempted where they cannot be perfectly developed, and it seems improbable that such could be the case where this part of the Fair now stands.

If, then, Chicago is willing to build appropriate structures around this basin and canals, the problem they offer will find a delightful solution. But they would have to be built from the ground up. The present ones, excepting the peristyle and its flanking halls would not be appropriate; and even if they would, they could not be preserved, for their walls are of lathing, not of solid brick, as are the necessarily fire-proof walls of the Art Building.

The mention of this building brings a regretful thought. For the purposes of the Fair its best place is its present place, and if it is preserved, we could not, for its own sake, wish to see it on a more beautiful site. But for the sake of the great formal garden which might be created around the basin and canals, one is tempted to wish that it had chanced to stand where the Administration Building stands. Then, a formal garden covering all this portion of the Fair-grounds would indeed be appropriate; and, especially if Mr. McMonnies' splendid fountain at the end of the basin could likewise be reproduced in marble, its general effect would indeed be one which any city of the world might begrudge to Chicago. But this is a dream impossible of realization. One can only hope that Chicago may see its way clear to preserving the Art Building where it is, and also to erecting other buildings which will justify the preservation of the basin and canals, and their inclusion in a great architectural gardening scheme.

Boston, Mass.

X.

[Whether or not great buildings are essential for formal gardening it is not our purpose now to discuss, but symmetrical arrangements are, without doubt, useful and appropriate wherever great crowds are to convene for any purpose. This seems to justify the Mall in Central Park and the Greeting in Franklin Park, Boston. We do not think, however, that the design of the Fair-grounds would justify any attempt to convert them hereafter into a formal garden. In the first place, if an artist wished to design an architectural garden with water in it he would very probably select a different form from the water scheme in Chicago, which relates to the great buildings about it, supporting them, exhibiting them to better advantage, and furnishing means of access to them. The basin with its arms is reasonable now with the buildings about it, but, no doubt, a hundred better plans could be devised if the water was meant to be part of a great symmetrical garden.

This makeshift propensity to force things to answer some end for which they were not designed and for which they are therefore but imperfectly adapted, seems to have become one of the acquired vices of our national character. Of course, it was natural, in so great a work as that at Chicago, that this propensity should manifest itself at once, and the fact is that a hundred enterprising persons

have set out to hunt up reasons and excuses for making the expedient and temporary structures of the Exposition to answer for some end which was not thought of when they were designed, and for which they can by no possibility be well adapted.

Besides this frontier feeling which "guesses we can manage to make it do," there is the thrifty suggestion that it is a great waste of opportunity not to use this great basin to some noble end. But the fact is that the walls of this great basin, like all the other structures, and even the grounds themselves, are of the most temporary character. As Mr. Olmsted has well stated, what they have been making in Chicago is a "camp"—a place to be occupied for a brief period only—and their work is good or bad as it is adapted to serve a definite purpose during that period, and no more. The Art Building is exceptionally substantial, but this is not so because it was meant to be fitted for any more distant and lasting purpose than the other structures, but because no valuable pictures would have been sent to a building which was not secure from injury by fire, tornadoes, mobs or earthquakes. What has been said of the temporary purpose of the structures in general applies with increased force to the canals, basins and terraces. The surface staff is laid upon a wall of slender piles and planking, which are only meant to be strong enough to hold up the banks for a year. Not only will the staff be peeling off and breaking soon after that, but the timbers and planks will be springing out and giving way, and in a few years natural forces will warp and crack and crumble the walls, and begin the work of establishing an irregular, meandering shore-line which is wholly agreeable as the boundary of water-courses in a park when it is prepared with a natural motive, but wholly unsuitable to an architectural garden.

Besides this, the apparent high ground of the Exposition is in reality nothing but deceptive ridges which enclose great craters now covered by buildings and terraces. There is not an acre of ground now having an architectural aspect upon which a piece of good permanent formal garden could be made without great outlay for grading and establishing fixed architectural conditions. Looking at the Fair-grounds as a site for a great public park for Chicago in future years it would be much cheaper to provide agreeable natural scenery than to perpetuate the conditions now seen on the grounds.—Ed.]

In the Redwood Forest.

To the Editor of GARDEN AND FOREST:

Sir,—The larger part of my summer vacation has been spent camping in the Coast-range upon a tract of eighteen hundred acres north of Russian River, reached by the North Pacific Coast Railroad from San Francisco, a line that has opened up some of the most attractive districts in California. The eighteen hundred acres, mostly covered by forest, are the property of William Montgomery, a well-known capitalist, and has been kept with great care, so that it would be a pleasure to live there for months instead of for weeks. Redwood groves, famous throughout California, occupy the "flats" along Austin Creek, and lesser, but still remarkable, forests fill the branch cañon. Along the eastern side of the tract the Oak country begins; toward the ocean the Redwood is more mixed with Douglas Spruce, and the Tan-bark Oak (*Quercus densiflora*) attains a larger size.

The atmosphere is dry and clear at this season, and the best place to pitch a tent is often in the deepest recesses of the forest, where only glimpses of the sky can be obtained. I had long had an idea that the Redwood forests were too damp for comfortable camping, and it may be so near the ocean, where the fog rolls in, but on Austin Creek, at least, any person fit to live outside of a hospital could make himself comfortable at this season. An old sailor who lived in a small cabin in the vicinity told me, however, that it "did rain awful every winter." Late in the autumn, too, as I learn, the insect-life of the forest is very annoying. July and August are almost free from these pests if one does not camp in the Laurel-clumps, which are said to swarm with various abominations.

Besides the Redwoods, there are beautiful tall Maples by the

stream and a solitary *Torreya Californica*, the only one in the region. Immense bushes of *Rhododendrons* in full bloom fairly line the banks. The distant effect is of white masses against the dark Redwood, but upon a nearer view the delicate buff markings tinge the white. Watson's description of *R. occidentale*, the California *Azalea*, mentions the "pale yellow bands upon the white or slightly rosy flowers." I have sometimes seen plants to whose flowers pale yellow applied, but the generality are marked with a distinct buff of various shades, depending upon age of flower, location, or minor variations of the species. Watson (*California Botany*) gives the height of *R. occidentale* as from four to six feet, but on Austin Creek, at least, it seems hard to find plants of less than eight or ten feet in height.

Several miles below our camp the Redwood forest was cut by lumbermen twenty or thirty years ago, and it has since partially grown up. This region possesses a peculiar interest to me because, more than any other place I know of, it shows the kind of reforestation that might easily be had with a little care from capable officials. If the fire had been kept out of several hundred acres along Russian River and Austin Creek, its tributary, there would be a fine and well-distributed growth of Redwoods there, for few cattle and sheep are in the region. The lumbermen left many old decayed trees, which sheltered the stumps, so that nearly all sprouted, and the young Redwoods are now loaded with seed. Richer soil could hardly be obtained anywhere, and if the fires which have swept through here nearly every other year were prevented, the second growth would be valuable.

In this old lumberman's camp, wild Blackberries, Raspberries and Currants have taken possession of acres. But the most remarkable feature is the extent to which the common Bigroot, *Megarrhiza Californica*, has become a drapery for stumps and fast-dying Redwoods. It is the Ivy of every deserted Coast-range lumber-camp. Twenty, thirty, forty feet above the ground, its star-like flowers, prickly balls and pale green leaves trail downward. In luxuriance of growth it almost rivals the wild Grape. But it stays in the clearings; you may search the deep forest for miles without discovering a plant of *Megarrhiza*.

In the early days of lumbering here, the Redwood-trees were cut at a height of twelve or fifteen feet from the ground, the best part of the trees being wasted. Many such stumps still remain and are being worked out for the lumber. In one case on Russian River, a stump fifteen feet high and sixteen feet across yielded fifteen thousand feet of lumber which sold at \$40 a thousand because it happened to be of especial beauty for cabinet-work. This stump was taken out by Colonel J. B. Armstrong, of Guerneville, who afterward told me the particulars. The labor of four men for three days was required to saw off the stump at the surface of the ground; then it was necessary to use eight yoke of oxen to drag the stump over. After splitting the log into four parts with powder, it was taken to the mill, and turned out, as I have said, fifteen thousand feet of "curly Redwood." If all the stumps paid like this, there would be work for many companies in the deserted lumber-camps, but it is easy to see that many are shattered, decayed or destroyed by fires. In cases where the lumber from the stumps is of no value, the cost of clearing bottom-land is from one hundred to four hundred dollars per acre. The fruit-growers along the Russian River usually spend from fifty to a hundred dollars "clearing brush," and plant their Prune and Peach orchards among the blackened stumps. Some of the finest fruit-trees I have ever seen were growing in this way. The soil is very deep and rich. No finer orchard-soil can be found anywhere.

The Foot-path Way. By Bradford Torrey. Houghton, Mifflin & Co.

The song of that light-hearted rogue, *Autolycus*, with whose peccadillos we are inclined to sympathize in spite of our Puritan inheritance, seems a little out of place upon the title-page of a volume which records the impressions and observations of a naturalist of the nineteenth century. For, in these days, we are nothing if not scientific—while the song from the *Winter's Tale* was written in the days before science was. Forever associated with the merry harvest-feasts of Bohemia, over which *Perdita* presided, it suggests that spontaneous delight in out-of-door life found now only in the child which has not yet borne the burden and heat of the day, or perhaps, in the tramp who evades them. But, since the paradise once lost may not be regained, and even our children's play-hours

must have some touch of serious earnest, it may be that the passion of the scientist will prove no unworthy substitute for the glories that have passed away. We are not surprised, then, that a walk over the "Foot-path Way," under Mr. Torrey's guidance, is no dreamy saunter over highways and hedges, with heart and mind passive and inert, and the senses only half-responsive to the myriad enchantments with which nature would woo the wanderer from his petty cares; but rather a rough scramble over hill and dale, "through bush, through brier," with every sense alert and vigorous, and the mind as keenly alive to the quest of the moment as if the fortunes of a state depended upon the observations taken during a morning's walk. This volume, like its predecessors, by the same author, "*Birds in the Bush*," and "*A Rambler's Lease*," consists of a series of essays on out-of-door topics, most, if not all, of which were first published in the pages of the *Atlantic Monthly*. To Mr. Torrey, all objects in nature, whether animate or inanimate, have both charm and significance, and though his own interest centres chiefly in birds, his eye is trained to note the grace and beauty of every way-side flower, and his ear quick to catch in the solemn music of the Pines "some accents of the eternal language" which he would fain interpret, if only with faltering accents, to his fellow-men.

But Mr. Torrey's love for birds is more human than ornithological, and bespeaks the man rather than the scientist. He studies them as individuals rather than "en masse"; delights in their idiosyncrasies and depicts their little virtues, or, perhaps, their vices, in a fashion peculiarly his own. For this reason the pages in which he records the manners and customs of his feathered friends prove very pleasant reading even to those who do not share his enthusiasm in his favorite pursuit. The information he gives is interspersed with flashes of playful fancy and occasional touches of genuine humor which would give charm even to a duller subject, and we cannot but envy him his enjoyment. "A happy man," he tells us, "is the bird-lover—always another species to look for, another mystery to solve. His expectations may never be realized, but, no matter, it is the hope, and not the fulfillment, that makes life worth having. How can any New Englander imagine that he has exhausted the possibilities of existence so long as he has never seen the Lincoln finch or the Cape May warbler? But I speak 'as a fool.' Our happiness, if we are bird-lovers, indeed, waits not upon novelties and rarities. All such exceptional bits of private good fortune let the fates send or withhold as they will," and so, though he feels all the scientist's enthusiasm for the "novelties and rarities" that fly across his path, he finds a sober certainty of waking bliss in watching the daily and nightly habits of the birds that from time immemorial have haunted the abodes of men.

In the paper entitled "December Out-of-doors," he writes very pleasantly of the kill-deer plovers, the presence of which in great numbers made the winter of 1888-89 famous in the ornithological annals of New England, but even his interest in this rare "find" does not blind him to the delicate winter loveliness of the vines and mosses, nor make him forget to note the sixteen sorts of wild blossoms to which December sunshine had given courage to brave December storms. In "A Widow and Twins" we have one of the prettiest bits of observation ever recorded in the annals of a naturalist. The widow is a tiny humming-bird deserted apparently by her mate at the time when she is most in need of his protection, and Mr. Torrey enables us to watch with eager interest the tender care she bestows for eight long weeks upon her mites of nestlings, until, at last, the period of infancy safely passed, all three fly away to some brighter clime, to return once more perhaps when the Honeysuckle is again in bloom. In "Robin Roosts" we learn the rather startling fact that robins fly for miles at nightfall to roost with thousands of their mates in some grove which has been chosen for the season as the nightly trysting-place of all the clan. The paper which shows the most true poetic feeling is that written in praise of the White Pine, which, for some reason he does not give, Mr. Torrey chooses to call the Weymouth Pine. For the moment he is above science and the objects of science, and is only conscious of the beauty of the solitary Pine and the impressive solemnity of the Pine-forest, dark, spacious, slumberous, musical. The lowly Partridge-berry and the showy Lady's-slipper attract him, for they are always the Pine-tree's neighbors, and with them he would listen to the murmuring leaves, which give utterance to musings and feelings that lie too deep for words. But these moods pass: "We are always in the presence of natural beauty, but only on rare occasions are our eyes anointed to see it. Such ecstasies it seems are not for every day. Sometimes I fear they grow less frequent as we grow older. We will hope for better things; but should the gloomy prognostications fall true, we will but

betake ourselves the more assiduously to lesser pleasures—to warblers and Willows, Roses and Strawberries. Science will never fail us. If worse comes to worst, we will betake ourselves to the moths.”

Notes.

It is estimated that the cemeteries of London cover an aggregate area of 2,000 acres, the value of which is not less than £2,000,000.

In the issue of *Gartenflora* for September 15th, it is noted that twenty-seven horticultural firms had thus far announced themselves to the Berlin committee as intending to exhibit at the World's Fair in Chicago.

Of the common shrubs that are valued for autumn color the Forsythias should not be forgotten. The deep chocolate color of the leaves just now is an admirable foil to the lighter and brighter tints of many species.

The most beautiful fruits in the market now are the Japanese persimmons. One variety, larger than a goose-egg, and with a smooth skin of a clear canary-yellow, seems to be as fair a product as any orchard ever yielded.

The product of some California orchards, as reported in a late letter to *The Tribune*, of this city, are somewhat astonishing. For example, a sixteen-acre orchard of German Prunes in Sonoma County, from five to eight years old, yielded 90,000 pounds of dried fruit this year and a net profit of \$7,500.

Several of the annual horticultural and pomological exhibitions usually held during September in north Germany have been officially interdicted, on account of the fear of cholera. This is especially regretted at Breslau, where not only an exhibition but a pomological congress was to have been held.

Among the plants that are conspicuous for their beautiful fruit just now are *Berberis Thunbergii*, *B. Sieboldii*, *B. Chinensis*, *B. Amurensis* and the yellow-fruited form of *B. vulgaris*. The *Prinos* section of the Hollies are also at their very best, especially *Ilex Sieboldii*, and *I. lævigata* with its yellow form. Some of the species of *Evonymus* are making a beautiful display in the Arnold Arboretum, especially the variety *Coccinea* of *E. Europeus* and the rose-colored variety from Japan. The fruits of many shrubs are so beautiful and last so long in good form that Mr. Jackson Dawson writes to suggest that some one should plant an autumn garden of shrubs which are especially valuable for their foliage and fruit.

A writer in a recent number of a Belgian horticultural journal speaks of the "veritable invasion" of his region this year by insects of the genus *Aphis*. "It is enough to make one believe," he declares, "that each plant has a species of its own, even weeds being attacked. Young and mature turnips, artichokes, endives, leaves and fruits—everything is threatened with death by this multitude of tiny parasites. Potatoes are not spared, but it is to be remarked that those which were sprayed with Bordeaux mixture have remained intact. In the nurseries fruit-trees and other species have suffered to the point of denudation. Copious irrigation, while it does not destroy the insects, invigorates the plants and enables them better to resist their depredations. A machine seems to be needed which will spray small plants from beneath with poisonous mixtures, since the clever aphides keep mostly to the under sides of the leaves."

In 1868 the "Portland Catalogue" of plants native to the state of Maine was issued by Professor Goodale and the Reverend Joseph Blake, and since then no complete account of the flora of this state has been published. It will, therefore, be welcome news to local botanists that a second and enlarged edition of this catalogue has just been issued, especially as the original one has become very rare. The new edition has been prepared by Mr. Merritt L. Fernald, and is a reprint from the *Proceedings of the Portland Society of Natural History*. It is simply a list in which the distribution of the more common plants has been noted by means of symbols, but it contains more than four hundred and fifty species and varieties of flowering plants and vascular cryptogams in addition to those named in 1868, the whole number amounting to more than one thousand five hundred and fifty.

In reply to an inquiry from the Boston Metropolitan Park Commission for information concerning statutes relating to parks, the chairman of the Berlin Committee on Parks, Gardens and Tree Plantations replied that in Prussia special laws relating to the laying out of public parks and gardens have

thus far been considered unnecessary, since every community has been alive to the desirability of such institutions, and, therefore, legislative compulsion has not been required. Travelers in Germany will bear testimony to the truth of this. In every city tasteful public gardens and parks will be found; choice landscape passages are carefully preserved and their beauty enhanced; and there are usually extensive public forests in the neighborhood, offering delightful recreation to the people, while the city draws profit from the timber and fuel cut there. May the time be hastened when our American communities will universally show their public spirit in the same enlightened manner.

Sub-irrigation has been tried in the greenhouses of the Ohio Experiment Station. Two beds, fifteen feet long and seven and a half feet wide, were floored with matched boards laid in white-lead so as to be water-tight, and the ends and sides were made water-tight. In the bottom of these benches three-inch tiles were laid two and a half feet apart, and arranged so that water could be supplied to each row as desired and six inches of soil were then placed on the benches covering the tiles out of sight. The effects of sub-irrigation upon the growth of Lettuce and Radishes were remarkable, and it was beneficial decidedly to Cucumbers. The first crop of Lettuce on the sub-irrigated beds was some thirty per cent. heavier than the crop on the bed treated in the ordinary manner, while the second crop showed a gain of fifty per cent. in favor of sub-irrigation. Radishes treated in this way came to marketable size earlier and were larger than those grown by the ordinary method. Nearly one-half of the sub-irrigated Radishes were ready to pull before one of the others could be used.

The colored frontispiece to the issue of *Gartenflora* for October 1st shows the portraits of two specimens of the Ontario apple, and is accompanied by a laudatory description written by Herr Carl Matieu, of Charlottenburg. The author says that this fruit, although described as early as 1885 in America, has not been hitherto noticed in Europe except by a single brief reference in a periodical published in 1888. On the 28th of April of this year, he says, he laid specimens of it before the Congress for the Promotion of Horticulture in the Prussian States. "The fruits were in the best condition, showing very slight, if any, signs of shrinkage, and yet had not been wintered in a cellar, but merely in a ground-story room with a northern exposure, laid on a layer of thick paper and shielded from the air only by two thicknesses of newspaper. They were cut from a tree trained on cords, four years old and about a metre in breadth, and from a pyramidally trained tree of the same age, and about a metre in height, and numbered in all twenty specimens." After explaining how easily this Apple may be grown in various ways, the writer adds that it is especially remarkable for its keeping qualities, for its delicious flavor and for the delicate substance of its flesh, which fits it admirably "for old people who have no longer any teeth which they can call their own."

At the forty-first meeting of the American Association for the Advancement of Science, held at Rochester, New York, in August last, Mr. L. M. Underwood spoke before the Botanical Club of "A Variety of *Polypodium vulgare*, new to America." "In the autumn of 1890," says the report of his words, published in the *Bulletin of the Torrey Botanical Club*, "my attention was called to a peculiar 'crispy' fern, growing on Mohawk Mountain, Connecticut, by Mrs. T. R. Waite, of New Haven, who had spent several summers on the summit of the mountain in the log-cabin established there for tourists. The plant proved to be a variety of *Polypodium vulgare* hitherto unknown in this country, but described from England as var. *Cambricum*. The plant is easily recognized by its deeply pinnatifid pinnæ, which are strongly in contrast with the normal entire pinnæ of typical forms of the species. This discovery is rendered more interesting by the announcement of the *State Botanist*, of New York, of a second European variety of this same species. Unlike var. *cristatum*, as figured by Peck and shown in the specimens kindly communicated by him, the specimens of var. *Cambricum*, as found on Mohawk Mountain in August, 1890, and again in July, 1891, were entirely sterile, not even showing rudimentary sori. The plants were growing on the sloping face of the granitic rock of which the mountain is composed, in small patches thoroughly entangled with plants of normal *Polypodium vulgare*. Environment is, therefore, not the cause of the variation in this instance, but it must be attributed rather to an inherent tendency to be something different. It is a question of interest to know just when to recognize a form of this kind as a true botanical variety."

Trees in October.

THIS year the beauty of the autumn landscape has been enhanced by the delaying of severe frosts and by a succession of windless days, which gives the final touch of perfection, like the bloom on a fruit, to the rich color which enwraps the woodlands. Though chilly nights have done their work, the days of early October were replete with sunshine and the temperature has been perfect, as if nature wished to aid the rejoicings of the Columbian year, and to that end had hung out her banners in more dazzling splendor than ever. Perhaps the dryness of the season has prevented the best development of the leaves, and in some cases marred their beauty. The absence of high winds, however, has kept the trees in foliage beyond the usual time, and made the outdoor enjoyment of them continually possible. To the tramping myriads in New York these days have been a priceless boon, as well as to the throngs of spectators who watched for hours the great processions on the natal day of the New World.

If a June day in New England is perfection, as the poet sings, that "rareness" is rivaled by these October days when earth and sky and air are once more attuned to perfect harmony, and the funeral pyre of the dying summer is robed with purple gold and flames with crimson and yellow fire. The variations of tint in even a small group of trees are wonderful. The scarlet of the Swamp Maple is relieved against the claret and bronze of the Ash; the bright chrome of the Beech melts into orange shading into red of the Rock Maple; the Oak, with its amber-bronze flushed with crimson, forms the deepest tone in this scale of color which is here and there relieved by the green of some slowly fading deciduous tree or the rich dark foliage of the Pines and Hemlocks. Upon the hills the Chestnuts turn to amber, the Scotch Larches hold aloft their tasseled branches of tawny gold, so that the frost-touched Hickories,

shriveled and brown, look dull beside them, while the dark blue Cedars stand up stiff and tall unchanged as yet by the cold.

Physiological botanists tell us that the kindling color in autumn leaves is due to the breaking up of the chlorophyll pigments into xanthophyll and erythrophyll, but if the man of science pursues the subject much beyond the giving of names to substances of whose composition he knows little, he soon reaches the absolute limit of his knowledge in this direction. We know that in our New England states these colors are much more brilliant than they are on the other side of the Atlantic, and our trees when transplanted to the gardens of Europe lose much of their autumn glory. It is supposed that our less humid climate in some measure accounts for the difference, and we know that the autumn coloring of the woods in a cool moist season, when lusty growth continues until freezing weather, is not so rich as it is in those years when the autumn air is drier and the sunshine brighter. Frost may hurry or modify this process of changing color, but it is not essential, certainly, because leaves often turn long before the frost appears. Thoreau says that color stands for all ripeness and that leaves before they fall acquire these bright tints just as fruits do when they mature. This is poetical analogy, however, and not science, for it is found that the changes in these two cases are caused by entirely different processes in the subtle chemistry of life.

But, whatever the causes of this marvelous change or however its processes are carried on, no one can look unmoved upon the splendid pageant. Our eyes never become weary of it, and every year it is witnessed with renewed wonder and delight. Individual trees and small groups of trees are strikingly beautiful in their way, but they cannot compare in magnificence with a great stretch of forest when it can be seen from above or when it sweeps up some broad mountain slope. Perhaps this is an insignificant point to be considered by those who wish to preserve our forests, and yet, if our woodlands are swept away in great breadths, the country would be robbed of a distinct feature of its autumn attractiveness. We should think lightly of Venice if she were ready to give over to the destroyer her acres of canvas rich with color and splendid in design. Certainly that man lacks patriotic pride who can see unmoved the destruction of miles of forest which every autumn paints in colors which would drive Titian and Veronese to despair if they should ever attempt to emulate them with brush and palette.

We have heretofore noticed the fact that individual trees of the same species often show marked differences in their autumn coloring. Close observation shows that these characters are persistent—that is, if the leaves of a certain Oak are more brilliant than those of any of its associates this year, they will continue so year after year. The general display may vary with the season, and, as a whole, it may be more or less brilliant, but these individuals always stand distinctly out from the others in effects of color. It is also true that sometimes the leaves on a single Maple-branch will turn scarlet, while the remainder of the tree is green, and it will do the same thing next year, and the next. Gardeners have perpetuated peculiarities of this sort with trees of abnormal color like the Purple Beech, or unusual habit of growth, like the Pyramidal Oak. Is it not a promising field of experiment to select certain trees with reference to the quality of their autumnal tints and secure a race of Maples or Oaks or Elms of unusual brilliancy? It might be found that the stock on which these cions were grafted would influence their coloring. It might be discovered that the peculiar brilliancy of individual trees is due to some chemical quality of the soil in which their roots feed. These certainly are matters which ought not to be left to conjecture. In the interest both of science and of art, the subject is worth investigation by our experiment stations, and there may be enterprising nurserymen who are willing to put the matter to practical test as a business venture.

A MEMBER of the well-known horticultural firm of Dammann & Company, near Naples, recently contributed to *Gartenflora* an interesting article on certain plants which, for centuries, have been called "Jericho Roses." These are natives of the deserts of Palestine, which, in ancient times, were thought to possess magical powers, because when they had long been in a desiccated condition they would at once expand and seemingly revive if immersed in water. Many specimens were brought home by the Crusaders, and so highly were they prized, for semi-religious reasons, that they were often represented in the paintings on old shields which still exist in France.

One of these plants, says the writer from whom we quote, is *Anastatica hierochuntica* of Linnæus, which belongs to the Cruciferae, and its name comes from the Greek *anastasis*, meaning "Resurrection." It was introduced into European cultivation in the year 1597, but the evidence of old armorial paintings shows that it was known, in imported specimens, at a very much earlier day, while ancient records tell that, in the time of the Crusades, a person who possessed such a specimen won wide distinction from the fact. "Drawn by the hot sun shining on the white sands of the desert," says our author, "into tight blanched balls, the dry twigs expand when placed in water just as a sponge does, or, indeed, any other desiccated plant. When again dried, the twigs contract once more, and this process may be often repeated during a period of several years. About a quarter of an hour is required for the unfolding, and the plant must be completely immersed, preferably in warm water." This "Jericho Rose," which, however, we are told is not the "true" one, is the only known species of its genus, but is most nearly related to our *Arabis* and *Cardamine*. Never attaining a height of more than eight centimetres, it spreads so widely that it sometimes forms a considerable bush, with a deep tap-root, furnished with but few rootlets, which eventually assumes a woody consistency. The outermost ones of its many stiff twigs curve inward, so that a characteristically developed specimen looks like a solid ball cut in two horizontally, and presenting a perfectly flat upper surface. The small white flowers are scarcely visible, and are usually deeply imbedded in the densely packed and somewhat fleshy foliage. The writer says that though this plant is reputed very difficult to cultivate, he has succeeded in raising specimens nearly half a metre in diameter, which look like smooth little green carpets.

The "true Jericho Rose," however, is *Astericus pygmæus* (formerly known as *Odontospermum pygmæum*, Neck.), which belongs to the Composite family. Although described by botanists only in recent times, it is, like the *Anastatica*, very faithfully pictured on old French crusading shields. Its name, of course, like that of our *Asters*, was inspired by the starry form of its blossoms. When dried, it has an absolutely dead and wooden appearance, but if placed in tepid water it expands entirely in the brief space of one minute, so that, in more superstitious ages than ours, it was very naturally accredited with non-natural powers. This Jericho Rose grows in the Canary Islands, in Africa and in Arabia, but with especial frequency in the deserts near the Suez Canal, whence, in a dried condition it is brought by the Bedouins to the bazaars of Jerusalem and the other cities of the Holy Land.

A picture of this *Astericus*, published with the article in *Gartenflora*, shows an apparently leafless plant, bearing, at the ends of stout flower-stems, a number of rather large fleshy star-shaped heads forming a flattened group around a larger central head, the arrangement recalling that of the familiar Stone-crop, which our children call "Hen and Chickens." Specimens may be obtained, our author informs us, from Herr George Eggers, of Joppa.

FOUR-score years have not sufficed to chill the enthusiasm or curb the enterprise of the veteran Robert Douglas, who has been making a trip on horseback over the Siskiyou Mountains to visit the famous Weeping Spruce (*Picea*

Breweriana). In a private letter he writes of this tree that, "to appreciate its appearance one must imagine a Norway Spruce from a hundred to a hundred and thirty feet high and three feet in diameter breast-high, with branchlets set thick together along each branch and hanging straight down sometimes to a length of six feet, although no larger than a lead-pencil at the point where they leave the limb." From a small twig which he kindly sent the foliage seems to be better than that of the Norway Spruce, not so long, but wider and thicker, and of a lighter and more cheerful green. The cones before they open are about as large as a man's middle finger. The seeds are small, although a trifle larger than those of the White Spruce, and Mr. Douglas estimates about 50,000 seeds to the pound. Several persons have tried to collect these seeds, but, so far as we know, Mr. Douglas was the first one to gather them, at least in any quantity. The trees stand on the steep mountain-side, and the cones are all on the very topmost branches of the tree and more than a hundred feet from the ground. In prospecting about this vicinity Mr. Douglas found a few trees that had not been discovered, so that in this station there are about a hundred full-grown trees. Standing where the snow lies over more than one-half of the year, and where the cold is very severe, they should be able to endure the severest eastern winters, although it is doubtful whether they would stand in a very dry atmosphere.

Notes of a Summer Journey in Europe.—XVI.

WITHIN a few years there has been a good deal of controversy in some foreign journals regarding the value of schools of horticulture and agriculture, and it is a subject of constant discussion among gardeners and farmers as individuals. Among a large class the idea seems to prevail that such institutions are of little value, that the teaching is theoretical rather than practical, and that graduates from these establishments are really less efficient and less valuable than men who have been working gardeners and farmers from their youth, and who have never been troubled by scientific considerations in their occupations. Another argument used against the school-training has been that the openings for specially trained men are extremely few, and that a graduate of a horticultural school has less chance of obtaining a good situation as gardener, at a satisfactory salary, than the man who never heard a lecture on botany, vegetable physiology or entomology, and who, moreover, would be willing to work for lower wages. But the old adage, "Knowledge is power," seems to hold here as in other occupations, and we find that natives of Germany, France, Belgium and other countries famous for their horticultural schools, are, in the majority of cases, to be found taking leading positions in matters relating to horticulture in almost every country in the world. It is true that two or three years of training in a school cannot produce a mature gardener, thoroughly experienced in all branches of his craft, but a good training will lay the best possible foundation for the acquirement of knowledge and the highest use of it.

One of the best of the French schools of horticulture is that at Versailles, being an institution founded and maintained by the Government. The grounds of the school were formerly, for about two hundred years, used as a sort of royal kitchen-garden, being laid out under the reign of Louis XIV. at a cost, we are told, of nearly a quarter of a million dollars. The total area is twenty-three or twenty-four acres. It is now about eighteen years since its foundation as a national school of horticulture, and already the records show valuable and interesting results in the number of pupils who have graduated as practical gardeners, and the responsible positions many of these graduates have taken in various horticultural and botanical establishments. About six hundred students have already received the benefit of a course of instruction here. The school is freely open to any one between seventeen and twenty-one years of age who can pass a satisfactory examination in the four ordinary studies of the common schools.

The course of instruction is completed in three years, and includes a general knowledge of botany, zoology, economic entomology, chemistry, geology and drawing, besides the subjects generally considered as pertaining to practical horticulture. If a student passes a satisfactory examination at the end of his course he receives a certificate from the Minister of Agriculture. Vacations are short, and the students perform

all the manual labor, in every detail, in the gardens and grounds, so that they get a thoroughly practical training as well as the knowledge derived from lectures and books. At the time of my visit, in early September, it was plainly to be seen that the practical part is done in a thorough manner, for, although many of the students were away on furlough, I found the place in fine condition, neat and free from weeds, the plants showing the result of good cultivation and care. The whole establishment is divided into neat beds and squares devoted to particular purposes, and there is also a considerable area covered by glass houses and frames.

In growing fruit-trees the artificial espalier system, so general in French gardens, is almost entirely resorted to; the plants grown are also very largely dwarfs. The system is one very rarely practiced among such fruits as Pears and Apples in our own country, but fruit of a very fine quality can be raised in this way. The small area of the school-grounds necessitates some such practice, because if normal trees were grown there would be space for but a very limited variety, and, moreover, the natural system would not suit the prevailing demand and necessity. It is stated that there are about twelve hundred varieties of fruit-trees and fruiting-shrubs grown in this garden. Of these nearly one-half are pears. This fruit has been so much cultivated and improved by Frenchmen that one almost regards pears as the national fruit of France, as the Fleur-de-lis is the national flower. There are more than three hundred varieties of Apples; of Peaches there are about a hundred and twenty-five varieties, while Apricots, Cherries, Grapes and other fruits are well represented.

A small piece of ground is used as an arboretum or collection of ornamental, shade and forest trees, and a good number of specimens have been accumulated. But the area available is so small that the plants hardly have nursery-space and are very much crowded, yet the collection may serve a useful purpose in assisting pupils to become acquainted with and to identify the various species and varieties, of most of which fine, well-developed individual specimens may be studied in parks and collections at other places in the vicinity of Paris.

In flowers this garden is probably most famous for its Roses, which were somewhat of a specialty with Monsieur Hardy, the late director, who did so much for the advancement of the school. His name and his father's name are commemorated in a most curious little single-flowered Rose, which is said to have originated in the Luxembourg garden more than half a century ago, by natural hybridization between *Rosa clinophylla*, a white-flowered Indian species, and the curious yellow-blossomed, simple-leaved *Rosa simplicifolia* from Persia and countries north and east of it. This odd little hybrid is known as *R. Hardyi*. As seen growing in the vicinity of Paris it seemed so dwarf and slender as to almost appear herbaceous, and its habit reminded me more of our little *R. foliolosa* than any other species. The stems of *R. Hardyi* are armed with a few stout straight spines; there are from five to seven small dark green leaflets to each leaf; and the flowers are about the size of those of *R. foliolosa*, but instead of being produced solitarily there are several on the end of each shoot. The petals are light or sulphur-yellow colored, the color deepening slightly from the tip toward the base; while the base of each petal, for nearly a fifth of its length, is of a dark crimson color. This Rose seems to bloom freely, and I saw it in blossom at Paris in the middle of July and again in early September. It is not likely that it would be hardy in our northern or New England states and I do not know that it has been tried here.

The greenhouses and forcing-houses are simple in construction but well calculated to serve the purposes intended. Nearly two hundred years ago, when it served as a pleasure and pastime for the King, this garden was famous for the early forcing of fruits and vegetables, but since then it is easy to imagine the great strides which have been made in improvement of methods and in the qualities of varieties.

The buildings used as class-rooms and for similar purposes are very simple in construction and arrangement and unpretentious in appearance. They contain a herbarium for constant reference; herbarium specimens which show the character of the injuries caused by particular kinds of insects and fungi; collections of beneficial and injurious quadrupeds, birds and insects; a very large number of excellent models of fruits; examples of seeds and other subjects of an instructive character. A well-selected series of woods of trees shows the character and appearance of important species when cut and finished in several different ways, while sections with the bark attached are intended to be helpful in the recognition of trees from the outward appearance of the stems. Altogether, the school seems admirably well fitted and conducted to carry out

the objects for which it was established. To fulfill the requirements here a student must work not only with his mind in the acquisition of knowledge from lectures and books, but he must share, and intelligently perform under competent direction, the manual labor and management of the whole establishment, for, as already stated, no ordinary laborers whatever are employed.

The surplus products of the school in the way of flowers, fruits, vegetables or plants are sold to the public, and the income thus derived forms no inconsiderable item to the state toward defraying the expenses of the establishment. Prizes in cash amounting to nearly two hundred and fifty dollars each are awarded by the Minister of Agriculture to those students who graduate with the highest honors, and it is generally expected that this sum will be spent in furthering their studies in some horticultural centres, as in the Netherlands or England.

The institution would, no doubt, be greatly benefited and its practical value increased by the possession of larger grounds for experimentation and work. This may come in time. Meanwhile the students are abundantly supplied with interesting examples and object-lessons in the gardens and nurseries which are so abundant in the country about Versailles.

Arnold Arboretum.

J. G. Jack.

The Mountain Flora of Alabama.

THE following paper was read by Dr. Charles Mohr, of Mobile, Alabama, before the Botanical Club at the meeting of the American Association for the Advancement of Science at Rochester last August.

The investigation of the flora of the Appalachian Mountains of the southern states has been chiefly carried on in the central and most elevated parts of the mountain-chain. Little has been made known of the floral conditions existing in its extreme southern outliers, which in relation to the distribution of plants in the eastern part of this continent are invested with a peculiar interest. Many plants, chiefly at home in high northern latitudes, follow the summits of the mountains into the warmer temperate zone and find upon these spurs the limit to their southward progress, while a number of others are confined exclusively to a single locality, or less frequently to several isolated localities.

The following remarks on the mountain flora of Alabama are based on observations made during the earlier part of this season in the mountainous region bordering upon the Tennessee Valley, on Lookout Mountain, near the north-eastern corner of the state, on the extensive table-land of the Warrior coalfield, with its steep escarpment forming the southern border of the Valley of the Tennessee, and on the detached outliers of the Cumberland Mountains, which form its north-eastern border. The region corresponding in the character of its flora with the flora of the higher mountain region of the adjoining states of Georgia, North Carolina and south-eastern Tennessee is in Alabama entered at an altitude not exceeding 2,000 feet above the sea. In the Lookout Mountain region this is indicated by a *Rhododendron* proper, *R. maximum*, the frequency of various other *Rhodoraceæ*, *Ericaceæ*, *Vacciniums* and several species of *Ilex*. This region is further characterized by the large preponderancy of deciduous-leaved trees, the almost entire absence of *Magnolias* and of coniferous trees in general, particularly of Pines of a decided southern range.

The somewhat abrupt declivity of Lookout Mountain, rising to a height of from 800 to 900 feet above Little Wells Valley, is covered with a tall forest, chiefly of Oaks, the species of the White Oak group prevailing. But a short time ago, it was noted for the abundance of fine timber of White Oak (*Quercus alba*), and for the tan-bark derived from the Mountain Oak (*Q. prinus*), but these resources are at present almost exhausted. The Black Locust has in these forests been for the first time recognized as a truly indigenous tree in Alabama. In the deep shade of the high forest on these declivities, several tall umbelliferous plants strike the attention of the observer, among them being *Ligusticum actiæfolium*, *Angelica hirsuta*, *Thaspium pinnatifidum*, with *Pimpinella integrifolia* and *Zizia serrata* smaller in size. *Oxalis recurva* and *Polygonatum giganteum* are for the first time noted within the limits of the southern flora associated with *Anemone nemorosa*, var. *quinquefolia*, *Stellaria pubera*, *Galium latifolium*, *Asclepias quadrifolia*, *Trillium erythrocarpum*, *Disporum lanuginosum*, *Uvularia grandiflora* and *U. perfoliata*. Emerging from the high forest at the base of the cliffs of the lower carboniferous sandstone, which border the brow of the escarpment, the southern *Philadelphus hirsutus*, *Ilex Monticola*, *Viburnum dentatum*, *V. acerfolium*, *Rubus occidentalis*, *R. Canadensis* and *Celas-*

trus scandens frequent the sunny heights. On the rocky flats of the table-land, where neither shrub nor tree is able to gain a foothold, *Arenaria brevitolia*, *Talinum teretifolium*, *Sedum ternatum*, and *Opuntia Rafinesquii* fill every hollow and crevice. *Senecio aureus*, var. *Balsamitæ*, frequent on the borders of wood-lands, becomes by its abundance a troublesome weed in the pastures and fields. *Rubus strigosus* covers low grassy banks. The forests on the plateaus of Lookout Mountain are open, the Mountain Oak frequently prevailing with Scarlet Oak. Post Oak (*Quercus minor*) and Black Jack (*Q. nigra*), Chestnut and Hickories are less frequently met with, and the Scrub Pine, *Pinus Virginiana*, the only one of its kind found in this part of Lookout Mountain, is seen in greatest perfection in detached groups. The springy soil in the gentle depressions of the table-land is covered by a most luxuriant growth of beautiful shrubs, and these also shade the rocky banks of the water-courses. In the first of these situations abound *Rhododendron arborescens*, *R. nudiflorum*, *R. viscosum*, *Calycanthus floridus*, *Ilex Monticola*, *Vaccinium virgatum*, and a peculiar form of *V. stamineum*, three to four feet in height, and, on account of its large edible berries, known by the settlers as the Wild Gooseberry, while the rocky banks of the creeks are preferred by *Rhododendron maximum*, *Kalmia latifolia*, *Calycanthus glaucus* and by *Viburnum cassinoides*. This shrub from the Saskatchewan Valley and the north of New England, extending to the sunny hills of Alabama, overshadows on the banks of Little or De Soto River the *Sarracenia*s and *Eriocaulon*s common in the lower south, such as *Sarracenia flava*, *Eriocaulon gnaphalodes*, and *Lachnocaulon Michauxii*, which have established themselves on the grass and sedge covered sands thrown up on the banks of the stream. *Diervilla sessilifolia* is frequent on the rocky hill-sides of the narrow valleys, with *Coreopsis verticillata*, *Bigelovia nudata*, var. *virgata*, *Galax aphylla*, *Thalictrum clavatum*, *Viola rostrata* and *V. striata* on the rocky shaded banks moistened by never-ceasing rivulets. *Thalictrum dioicum*, *Asarum Virginianum* and *Saxifraga Virginiana* prefer rocky ledges and hill-sides covered by a drier soil with *Deschampsia flexuosa*, *Festuca nutans*, *Danthonia compressa*, *Eatonia Pennsylvanica* and *E. Dudleyi*. *Asplenium Bradleyi*, sparsely scattered throughout the Cumberland Mountains of Tennessee and southern Kentucky, has been found on the damp base of deeply shaded rocks. *Asplenium pinnatifidum*, *A. montanum*, *A. Ruta-muraria* and *Cheilanthes vestitata* prefer exposed cliffs, and *Adiantum pedatum*, *Aspidium marginale*, *Dicksonia punctilobula*, *Cystopteris fragilis* love shaded ravines.

Of the sixty-two species of vascular plants, outside of the forest-trees common everywhere, observed in this higher mountain-region, thirty-five, or fifty-six per cent., are most frequently distributed in the northern states; fourteen species, or twenty-three per cent., have a pronounced southern distribution, and twelve species, or little less than twenty per cent., are typical southern plants.

Descending from the higher mountain region to the table-lands and ranges capped by the conglomerates of the coal-measures, not exceeding in their average elevation 750 feet above the sea, the character of the vegetation changes with the frequent appearance of evergreen conifers among the deciduous-leaved trees of the forest. The Short-leaf Pine (*P. echinata*) crowns the ridges of a meagre and dry soil, and the Loblolly Pine covers the damp depressions, devoid of drainage, of the table-land; upon these swales, from a fraction of an acre to several in extent, this tree arrives at the best of its development and furnishes the greater part of the lumber-supplies drawn from this region. The Scrub Pine is here rarely seen, and the Mountain Oak much less frequently met with, while the Black Oak (*Quercus tinctoria*), Spanish Oak, Post Oak, Scarlet Oak, with the Chestnut and Mockernut Hickory, prevail in the closer soils of the table-land. Oaks of semi-persistent foliage, like *Q. uliginosa* and *Q. Phellos*, make their appearance in the coves and along the banks of streams; *Magnolias* take a prominent place in the forests of the elevated valleys beside the Black Sugar Maple, Ohio Buckeyes, huge Poplars, White Ash and White Oak. In a valley with such a tree-covering on Sand Mountain, near the western border of this region in Alabama, was *Magnolia cordata* discovered in 1880; a tree with characters but little understood before that time and its distribution involved in obscurity. From the Alabama specimen, it was evident that it was wanting in specific characters to separate it from *M. acuminata*, and it was hence admitted by Professor Sargent as *M. acuminata*, var. *cordata*, in the *Silva of North America*. On the rocky banks of the middle fork of Sipsey River, a tributary of the Warrior River, in connection with the valley in which the yellow-flowered *Magnolia* finds its secluded home, are found

groves of stately Hemlocks along the course of the creek to its junction with the main stream for a distance of from twelve to fifteen miles, where this tree reaches its southern limit. It is remarkable to find on this, its extreme and perfectly isolated outpost, the Hemlock associated with the Cherry Birch (*Betula lenta*), one of its companions in its northernmost home. Of trees of smaller size are to be mentioned *Oxydendrum arbo-reum* and *Halesia tetraptera*; of shrubs, the *Azaleas*, common in the higher region, to which are to be added *Stuartia pentagyna*, *S. Virginica*, *Ilex mollis*, *I. longipes*, *Robinia hispida*, var. *Elliottii*, *Andromeda ligustrina*, *Vaccinium virgatum*, *V. vacillans*, *V. arbo-reum* and a host of Hawthorns, *Cratægus spathula*, *C. coccinea*, var. *mollis*, *C. Crus-galli*. The rare *Dar-beya umbellata* is endemic in this lower mountain region of Alabama, Georgia and North Carolina, and it is only from the station recently discovered in the latter state that pistillate plants have become known.

The crescent-shaped cavities, worn by the action of running water in the perpendicular walls of sandstone enclosing the deep gorges and narrow valleys so frequently intersecting the table-lands, give shelter to the most delicate and rarest of Ferns; *Trichomanes radicans* covers with its rooting-stems the walls of these gloomy recesses, called rock-houses, dripping with moisture, never reached by a direct ray of the sun, protected against sudden changes of temperature and aerial currents. The tiny *T. Petersii*, forming dense mats resembling in its habit a Liverwort, is found solely in their darkest and most hidden recesses. On the threshold rocks to these caverns *Heuchera Rugelii* is chiefly found; and on the exposed sandstone rocks *Silene rotundifolia*, *S. Pennsylvanica* and a variety of Ferns, such as *Cheilanthes Alabamensis*, *C. tomentosa*, *Asplenium parvulum* and *A. pinnatifidum*. Fully twenty-five per cent. of the plants so far observed in this lower mountain region are very rarely, if ever, found north of latitude 36° 30', the line that separates the northern and the southern flora of eastern North America.

On the lower flanks of the mountains, where the outcrops of the mountain limestone form rocky declivities, and upon the calcareous lower hills the aspect of the flora is totally changed. The Red Cedar replaces the Pine among the deciduous trees, and in the most rugged localities occupies the ground exclusively, its dark foliage denoting in sharp outlines its presence at a distance. North of the Tennessee River in the openings of the dense Cedar-glades the surface of the flat rocks in the early days of spring is covered with the *Draba Caroliniana*, *D. brachycarpa*, *Leavenworthia Michauxii*, *Claytonia Virginica*, *Arenaria petula*, *A. serpyllifolia*, *Bellis perennis*, *Ranunculus fascicularis*, while the more open woods and copses of the hillsides, with a more varied tree-growth, present an array of herbs and annual plants rich in the varied hues of their flowers, such as *Sedum pulchellum*, *Cynoglossum Virginicum*, *Lithospermum tuberosum*, *L. canescens*, *Phacelia bipinnatifida*, *P. fimbriata*, *Salvia utricifolia*, *Scutellaria versicolor*, var. *mollis*, *S. serrata*, *Monarda fistulosa*, var. *mollis*, *M. Bradburiana* and *Opuntia Rafinesquii*, followed by the golden-flowered *Hypericum* (*H. aureum*) and *H. cistifolium*. Among the shrubs characteristic of the flora of these calcareous ridges are *Forestiera ligustrina*, *Rhus Canadensis*, and *Symphoricarpus vulgaris*, while among the trees confined in Alabama to the ranges of the mountain limestone among the outliers of the Cumberland Mountains are *Cotinus Americanus*, *Æsculus glabra* and *Fraxinus quadrangulata*. *Fraxinus Americana*, var. *microcarpa*, found to extend to the cretaceous hills in the centre of the state, occurs here with its fruit-bearing perfect seeds. This pretty tree, not exceeding twenty-five feet in height, with its widespreading limbs and drooping branches, can, therefore, not be regarded as a hybrid, and by the constant character of its fruit appears to be a proper species. As such it has been recognized first by Vasey, who, in his catalogue of the forest-trees of the United States, mentioned this tree under the name of *Fraxinus Curtisii*. *Cotinus Americanus* has been found on the summit of one of the highest limestone ridges near Gurley to cover tracts of several acres in extent, and there seems no doubt that this beautiful tree is found in such situations upon many of these detached spurs of the Cumberland Mountains in Alabama.

The three great functions of mountains—those of giving motion and change to water, air and earth—are indispensable to human existence. And thus those desolate and threatening ranges of dark mountain, which in nearly all ages of the world men have looked upon with aversion or with terror, are sources of life and happiness far fuller and more beneficent than all the bright fruitfulness of the plain. The valleys only feed; the mountains feed and guard and strengthen us.—*Ruskin*.

Plant Notes.

Aristolochia Sipho.

IN the illustration on this page is shown a fine example of the well-known Dutchman's Pipe, *Aristolochia Sipho*, as the broad leaves are seen relieved against the mat of Japanese *Ampelopsis* close against the walls of the house. The plant is striking here, but its luxuriant growth shows that it can be used to even better purpose where a covering is needed for a trellis or wall or wherever else a good thick screen is a desideratum. Although well known, the Dutchman's Pipe is much less frequently seen in gardens than would generally be supposed.

An inhabitant of the Allegheny region so rich in trees and shrubs, from Pennsylvania southward, it proves perfectly

This dense leafage pretty effectually conceals the curious brown-colored flowers, an inch and a half long, and of a shape resembling a siphon, or Dutch pipe, from which likeness the plant derives its specific and popular names. As the *Aristolochias* are without petals, the curious flower-tube is simply the calyx. The fruit is a six-angled, oblong capsule, two or three inches in length, and it is said that the seed does not long retain its vitality. Fruit seems to be uncommon or rarely produced in northern gardens. Where fresh seed is not available the Dutchman's Pipe may be propagated by layering or by cuttings in sand, under glass and with some bottom-heat.

We have many other vines, suitable for coverings or screens, whose foliage is more pleasing and graceful than this, which is somewhat coarse in appearance, but there is a solidity about it which makes it peculiarly appropriate in

Fig. 86.—*Aristolochia Sipho* on the house of Mr. S. B. Parsons, Flushing, Long Island.

hardy in most parts of New England and will thrive even as far north as Montreal. In fact, the St. Lawrence Valley is much more favorable to plants of doubtful hardiness than many other regions farther south.

Aristolochia Sipho grows and thrives best in a deep, rich soil, and in most situations requires no protection in winter. As it is a twiner, and not a climber like Ivy, it will not grow up a blank wall without poles, wires or some other such objects, about and among which the stems may twine. The stems are very pliant and tough and may be freely handled or trained in any direction without fear of breaking. The very thick, large, roundish heart-shaped leaves are often a foot in length and eight inches wide, and when in full foliage the plant forms one of the most perfect and dense screens which can be grown on a trellis.

some situations. It seems to be very little affected by fungous or insect diseases.

Aristolochia tomentosa is another hardy species, with much the same habit as *A. Sipho*, but it is a much more slender plant, with lighter-colored and very much smaller leaves and smaller flowers of a brownish or greenish yellow color, with a deep purplish colored tube. The Dutchman's Pipe appears to be little, if at all, used medicinally as is the Virginia Snake-root (*A. serpentaria*) and others of the same genus, both in this country and the Old World.

The greatest number and the finest representatives of the genus are inhabitants of the tropics, and chiefly of tropical America. Figures of one of these were given in the third volume of GARDEN AND FOREST (pp. 598 and 599)

under the name of *Aristolochia grandiflora*, or Pelican Flower, which Mr. Watson of Kew afterward (vol. iv., 546) stated should be known under a different specific name, or *A. Gigas*. Large specimens of these blossoms, in cultivation, have measured eighteen by twenty-two inches across the face of the open flower, and, moreover, they are provided with a curious tail-like appendage three feet long. The forms of the flowers of these exotic species are quite as strange as in our Dutchman's Pipe, those of *A. Gigas* resembling a pelican or duck, especially when in bud. They seem to be constructed so as to entrap insects, and many of them give out a very strong and disagreeable odor.

We ought to add that our illustration is a view of the house of Mr. S. B. Parsons, of Flushing, Long Island, and that on another part of his grounds the *Aristolochia* which shows so well in this picture is used with great success to form such a screen as we have spoken of. In the pretty composition in this picture the tree at the left corner of the house is a thrifty young Kentucky Coffee-tree, which illustrates well the open character of its foliage at this stage of growth. The two plants in the foreground of the extreme left are a Japanese Juniper and a golden-tipped *Arbor Vitæ*. The compactly grown shrub in the centre is a good specimen of *Berberis Thunbergii*, and the plant at its right is a pyramidal *Arbor Vitæ*.

Yun-nan Rhododendrons.

THE current number of *The Garden* contains an admirable illustration of *Rhododendron racemosum*, which is a charming little plant, and since it is likely to be quite hardy in England, it will be a first-rate plant for the rock-garden. It is not more than nine inches high, with healthy bright green leaves an inch long clothing the entire stems. The flowers are terminal axillary clusters nearly an inch across, pale pink, margined with rose, and slightly fragrant. The plants in cultivation all came from the same batch of seeds, which were sent to Paris from Yun-nan by the French missionary Delavay. There is some doubt as to the correct name of this plant, but, whatever it may be, the plant is a welcome addition to our garden treasures. In fact, it seems that the Yun-nan Rhododendron may prove quite as useful in the garden as the Himalayan and Malayan species. Altogether there are some sixty-five species of Rhododendrons in China so far as is known, including such old species as *Rhododendron Fortunei*, *R. Dauricum*, *R. ovatum* and the so-called Indian *Azalea*. These Chinese Rhododendrons are not so magnificent as the giants of the Himalayas, but they have a charm of habit, flower and color which is their own.

New or Little-known Plants.

Cypripedium Warnero-superbiens.

THE new hybrid *Cypripedium* illustrated on page 511 was described in the *Gardeners' Chronicle* for September 10, 1892, by Mr. Robert M. Grey, gardener to Mr. H. Graves, Orange, New Jersey, in whose collection it has recently bloomed. This Orchid, *C. Warnero-superbiens*, was said to be intermediate between its parents, with foliage five inches long, acute, broad near the base, reticulated with dark green on a pale ground. The flowers are solitary, on pubescent brown scapes, the dorsal sepal proportionately large, white with radiating green nerves and a stain of vinous red across the centre. The inferior sepal is much smaller and of the same color. The petals are narrow, white, tinted with vinous red at the apices and closely veined with green, ciliate and warted on the margins, with an occasional spot on the surface, and some brown specks near the base. The lip is of a rich glossy brown color, slightly concave below the opening and speckled on the unfolded lobes. The staminode is pale green, with darker green reticulation.

New Orchids.

ODONTOGLOSSUM OWENIANUM, Rolfe.—A distinct and pretty *Odontoglossum* which flowered in the collection of Messrs. F. Sander & Co., of St. Albans. The sepals and petals are yellowish white, the former with the whole of the disk chocolate, and the latter with or without a chocolate blotch. The lip, which approaches that of *O. Pescatorei* in shape, is wholly white. It may be a natural hybrid. *Gardeners' Chronicle*, August 13th, p. 178.

ZYGOPETALUM GRAMINIFOLIUM, Rolfe.—An elegant little species allied to *Z. maxillare*, Lindl., with narrow leaves and an erect raceme of largish flowers. The sepals and petals are light green, heavily blotched with dark brown, and the lip of a uniform bright purple-blue. It is a native of South Brazil and was imported by Messrs. F. Sander & Co., with *Lomaria Boryana*, on the trunks of which it creeps by its slender rhizomes.—*Gardeners' Chronicle*, August 13th, p. 179; *Lindenia*, t. 339.

LÆLIA × *OWENIANA*, Hort.—A very pretty hybrid raised from *Lælia pumila* Dayana crossed with the pollen of *L. xanthina*. The sepals and petals are white, the tube of the lip bright yellow, and the limb dark maroon with a white tip. It was exhibited by Messrs. F. Sander & Co., of St. Albans, at a meeting of the Royal Horticultural Society on August 9th last, and received an award of merit.—*Gardeners' Chronicle*, August 13th, p. 191.

LÆLIO-CATTLEYA × *INGRAMII*, Hort.—A fine hybrid raised from *Lælia pumila*, var. *Dayana*, crossed with the pollen of *Cattleya Dowiana*. The sepals and petals are light rose, and the lip dark purplish crimson with an obscure lighter tracing. It was exhibited by C. Ingram, Esq., of Godalming, at a meeting of the Royal Horticultural Society on August 9th last, and was awarded a first-class certificate.—*Gardeners' Chronicle*, August 13th, p. 191.

VANDA VITELLINA, Kranzlin.—A species allied to *V. coerulescens*, Griff., but with yellow flowers of far smaller size. It was imported by Messrs. Seeger & Tropp, of East Dulwich, and flowered in the Royal Botanic Garden, Berlin.—*Gardeners' Chronicle*, August 20th, p. 206.

CATTLEYA × "BARONESS SCHRÖDER."—A hybrid raised between *C. Triance* and *C. dolosa* in the collection of Baron Schröder, of The Dell, Egham. The sepals and petals are veined and tinged with clear rose-pink, and the lip white with rose-colored margin and an orange throat. It was exhibited at a meeting of the Royal Horticultural Society on August 23d last, and was awarded a first-class certificate.—*Gardeners' Chronicle*, August 27th, p. 249.

EULOPHIOLLA ELISABETHÆ, L. Lind. & Rolfe.—A very interesting and handsome new genus, with something of the habit of *Catasetum*. It has an arching raceme of largish white flowers, with some maroon-purple on the back of the sepals and a deep yellow disk to the lip. The pedicels and the entire scape are of a deep lurid vinous-purple. It was introduced by Messrs. Linden, L'Horticulture Internationale, Brussels, and flowered in their establishment.—*Lindenia*, t. 325.

Kew.

R. A. Rolfe.

Foreign Correspondence.

London Letter.

PRUNUS JACQUEMONTII.—This is an interesting species of Plum, the introduction of which we owe to Dr. Aitchison, who sent seeds of it from Afghanistan to Kew, where it flowered in May, 1887, and was figured in the *Botanical Magazine*. It has fruited freely this year, and is now a conspicuous ornament in the Arboretum, the rich crimson fruits, as large as those of the Cherry Plum (*P. myrobalana*), being abundant on the twiggy spineless branches, upon which the brown tinted ovate leaves still remain. The fruits are in appearance as tempting as cherries, but their taste is not agreeable, being acid and astringent. The plant is, however, worth growing to look at. According to Hooker, it is the plant referred to by Brandis in his *Forest Flora*,

p. 194, under *P. humilis*, and described as a small glabrous shrub, with brownish gray bark, ovate-lanceolate, coriaceous, deep and sharply serrated leaves, fimbriate and often bifid stipules. It is found in the drier region of the north-west Himalaya, at an altitude of 9,000 to 12,000 feet. *P. Jacquemontii* fruits freely when small, plants less than a yard high being heavily laden with fruit, and it is quite hardy; it might be worth crossing with some of the garden plums, which would be improved in flavor by the addition of a little acidity. The stone of the fruit is small, nearly globose, and almost smooth.

PUNICA GRANATUM, var. *NANUM*.—This is a charming little shrub, which, in England, is much superior to the type, as it flowers freely, whereas the latter does not. In some German towns the dwarf Pomegranate is a favorite deco-

dense raceme of white flowers half an inch long; the tube is constricted at the base, then widening upward, and divided at the top into six regular segments; filaments a little longer than the tube, anthers yellow. This plant is a native of Griqualand, east, at an altitude of 6,000 feet. It may prove to be quite hardy in England. It is pretty when grown in pots in a greenhouse, and thrives in a sunny border in the open air, where, as well as in the Cape-house, it is now in flower. It is sure to receive the attention of those specially interested in Kniphofias.

GERBERA JAMESONI is still flowering in a sunny border in the open. The flowers, though a less brilliant scarlet, are quite as large as those produced in midsummer. Several years are necessary for this really beautiful Cape Composite to become established, but it is quite worth waiting for.

Fig. 37.—*Cypripedium Warnero-superbiens*.—See page 510.

rative plant, being grown and used as *Solanum capsicastrum* is here. At Kew it is planted outside in a sunny border, where it grows to about one and a half feet in height, and now, in October, it is covered with beautiful scarlet fleshy flowers. Lifted and planted in pots these little shrubs are most useful for the conservatory. The flowers are double.

KNIPHOFIA MODESTA.—This is a white-flowered species, which was named and described by Mr. J. G. Baker, in the *Journal of Botany*, 1889, p. 43, and of which plants and seeds have this year been sent to Kew from Natal. It is a pretty plant, with linear keeled leaves a yard long, glaucous green, smooth-edged and soft in texture. The peduncle is slender, erect, three feet high, the upper foot a

The handsome green leaves and stout blooms produced by vigorous plants are much superior to those on a weak plant. In a sheltered sunny corner plants of it have now stood outside, winter and summer, for three years without suffering any apparent injury from cold. I consider *G. Jamesoni* one of the very best of the newer introductions from South Africa. Unfortunately, it has so far failed to ripen seeds here, and, as it grows slowly, division of the root-stock is not a quick means of working up a stock. Nevertheless, it is a plant worth looking after. Each flower is two and a half inches across, colored the most brilliant scarlet, and it lasts at least a month.

NYMPHÆA MEXICANA.—We have several times had tubers of this plant from American correspondents, but in each

case they have turned out to be *N. gracilis*, a white-flowered species not unlike the white *N. stellata*, which was distributed a year or two ago as *N. Voalefoka*. A tuber of the true yellow-flowered *N. Mexicana* sent to Kew would be most acceptable, and, if the sender desires, the gift would be reciprocated. The Floridan *N. flava* has been in cultivation at least ten years here, but it flowers only rarely. I am told that *N. Mexicana* is much freer in bloom, and also a darker yellow, than *N. flava*. The seeds of these plants retain their vitality several years if kept quite dry in a packet. Some growers I know keep them in water in bottles, but the effect of this is to make all germinate within the year.

EUPHARIS STEVENSII.—This plant is supposed to have originated from *E. candida* crossed with *E. Sanderi*, but, judging by a plant of it now in flower at Kew, it scarcely differs from *E. Sanderi*, of which a figure will be found in the *Botanical Magazine*, t. 6676. I am inclined to believe that nearly all these so-called species of *Eucharis* are merely seedling forms of one variable species. If any one will take the trouble to raise *E. grandiflora* (*Amazonica*) from seeds he will probably get plenty of variations quite as pronounced as those shown by such questionable species as *E. Sanderi*, *E. Mastersii*, *E. Bakeriana* and *E. candida*. There is only one really first-rate *Eucharis*, and that is the common *E. grandiflora*; the rest may be called more or less inferior varieties. It is remarkable that the habitat of typical *E. grandiflora* has never been found since it was first discovered by Triana, who sent to Linden in 1854 the bulbs from which all the thousands now cultivated have sprung.

THE BELLADONNA LILY.—I have more than once written of this plant as one of the first attractions in the borders at Kew and a few other English gardens in autumn. There are now several hundred spikes of flowers on a south border against the Orchid-house here, where they make a rich glow of rose-red color. I write now to recommend growers of bulbs in America to take up the Belladonna and raise it from seeds. Hitherto we have relied solely on bulb offsets for the multiplication of this plant, consequently we have not improved it at all. That it is capable of considerable improvement by means of seeds and selection is evident from a plant, a seedling, flowering at Kew now. This plant was obtained several years ago as a probable hybrid between the Belladonna and *Brunsvigia Josephinae*. On flowering, however, it proves that the supposed cross did not take place, the plant being unquestionably a pure Belladonna. But such a Belladonna! The scape is as thick as a man's thumb, a yard high, and it bears an umbel of twelve flowers all open together, half as large again as the ordinary form, and colored a rich rose-red, very nearly crimson. Every one who has seen this plant declares it the finest Belladonna Lily ever seen. We propose to call it variety *Kewense*. This *Amaryllis*, which, by the way, I may observe, is the only true *Amaryllis*, has been in cultivation since 1712, when it was introduced from South Africa.

We do not employ the seeds of bulbous plants for purposes of propagation nearly as much as we might. Cultivation, in a garden sense, generally has the effect of improving plants, but it is only when the plants are raised generation after generation from seeds that the law of variation is called into action. Branch or bud sports are extremely few and rarely occur, but seedlings often show a great deviation from the parent.

A Few Neglected Grapes.

IN our ambition for new sorts and improvements we are apt to overlook some of the best of our old fruits. This is especially true of Grapes. Among white Grapes I doubt if we have yet one which, altogether, is more worthy of a place of honor than Martha. It grows well, and when dead-ripe is sweet and refreshing. It has no hard pulp, and is not over-

supplied with seeds. The berries stand out well shouldered, and get to be a fine translucent greenish white. In quality it is far ahead of Niagara, and in ripening much more reliable than Diamond. Nor is it inclined to any disease. For three or four years Martha has grown in favor with me.

Hayes is a richer grape than Martha and two weeks earlier, but it is not a good grower nor an abundant bearer. I think it decidedly the highest-flavored of our white grapes that I have tested for vineyard culture. In this respect it has but two rivals, Eldorado and Lady, neither of which gives good crops, as a rule. Lady is earlier, and, if a good cropper, should be rated as the most remarkable of all our grapes for quality and earliness. Eldorado is later, and of very fine quality; Hayes intermediate. But from the first translucency Hayes is sweet enough to eat, which cannot be said of most grapes, especially of Diamond.

A third grape liable to be crowded out is Duchess. This is a pure, sparkling, crisp grape, never sugary, but rich and very satisfying. My children select the Duchess from forty varieties. A disadvantage of this grape is that you cannot easily tell when it is ripe, and if left on the vines when ripened cracks and decays. It is not a good market grape, while very desirable for home use. There is no more prolific Grape; it bears huge bunches as handsome as hot-house varieties. The bunch is very compact, and is very rarely touched with rot.

Brighton should hardly be noted as likely to be crowded out, for in some quarters it is getting new attention. But there is for the vineyard, in my judgment, not one finer Grape than Brighton. The bunches are very large and handsome, just compact enough, and of most delicious quality. When planted alone it is a barren vine; when alternated with Niagara, Pocklington, Worden or Duchess it bears marvelously. It is capable of wonderful crops. The grape is, however, not a good keeper. Its parent (*Iona*) is, on the contrary, one of the best keepers. I shall steadily throw out a large number of varieties, replacing with Brighton.

Golden Pocklington is another worthy Grape that has been crowded too hard by Niagara, and deserves to be replaced in a selected list. It is a large grape of good quality, decidedly better than Niagara. If closely pruned it ripens about the same time as the Concord. Its tendency is to bear very heavily, with fine compact bunches; it has little inclination to any sort of disease.

A Grape rarely mentioned is August Giant; it is huge and of enormously rampant growth. The vine is very healthy and very hardy, and will cover a barn in five years. The bunches resemble Herbert, and the flavor is excellent. The skin is thick, and the grape is a good keeper. I have seen some tendency to mildew in shady places, but not much. I should class it with Herbert, although it is far from being as good as that magnificent fruit. Herbert is not a perfect self-pollinizer, but does fairly well. I plant Duchess with it. The flavor is pure, and there is no sour core. The skin is very thick; it is a good keeper.

One more overlooked Grape is Goethe (*Rogers No. 1*). It deserves to rank number one for all reasons. No other *Rogers* hybrid surpasses it, if any equals it. As far north as this it cannot be grown in vineyards; but a few degrees to the south the Goethe is the most delicious of the meaty varieties, as *Iona* is of the juicy sorts.

E. P. Powell.

The Vegetable-garden.

OUR first sowing of the rose-colored Chinese winter Radish is now in use (October 15th), and our last sowing of seed of the same was made to-day. This sowing will be in use the greater part of the winter. Those who are fond of radishes should always use this variety in autumn. To many people it is better than most summer sorts. Those who have never used Radish-tops as a salad or as boiled "greens," should know that in a young state the thinnings of the crop make an admirable salad, cut up root and top together, while the more matured tops boiled with a bit of bacon are relished by any who are fond of "greens." One great advantage is the short time required to get a crop of greens for the table. Kale and Spinach, sown at the same time with these fall Radishes, will not furnish leaves for boiling for some time to come, and in the mean time the Radish-tops are useful, and, to my taste, much better than any kale. In northern localities these winter radishes should be lifted and stored before hard freezing sets in. Here the best plan is to mulch them with straw or pine-leaves to protect the soil from freezing, and they can be pulled as needed.

We were quite pleased with our little experiment with the English Broad Bean as an early green vegetable. Our seed was planted in a sunny situation in January. They soon came

up and grew with the utmost indifference to the weather. In fact, they were subject to quite hard-freezing when in bloom without injury, and the green beans were ready for shelling before the early peas. Some folks laughed at the idea of eating "horse-beans," but I found them quite palatable while green. They soon succumbed to warm weather. The Italians here use them largely, planting in December. We would advise a trial of these, planted at the usual time for planting English Peas in the north.

The time for storing cabbage for winter in the colder sections is near at hand. Some like to keep the stalks over for sprouting spring greens. For this purpose heel the cabbages in a furrow and pack the earth well around the base of the head. Pack the rows closely together so as to make compact beds five or six feet wide. Then thatch them over closely and thickly with evergreen boughs, and they will usually winter well. When no account is taken of the stalks, plow out a deep furrow in a dry place and place the cabbage in it root upward and the leaves of the head well tucked under. Then plow furrows from each side, and finish with a sharp and smoothly patted ridge over the row. This I consider the best method in any locality where a zero temperature occurs. Here the most expeditious way is to turn each cabbage on its side without pulling it up. Turn the head toward the north, and then cover the stem and base of head with earth. This should be done just after Christmas.

On the approach of winter, if your vegetable-garden soil is of a clayey character, you will find your spring work greatly facilitated, and the soil in much better condition all the next summer, if it is thrown into sharp narrow ridges with a plow, and left thus all winter for the frost to act upon it. These ridges will get very mellow, and will dry out earlier in spring than a flat surface, and they can be worked down and planted a week or two sooner than the land of your neighbors who do not take this precaution. It is easy enough to beat folks northward of you in earliness of products, but the skill of the gardener is best shown by the foresight which enables him to get in advance of his immediate neighbors.

We have now (October 17th) green peas in great plenty from a sowing of Premium Gems in August. There has been but one good rain since they were planted, and yet the vines are fresh and green and clear of any signs of mildew. Yorkshire Hero is just in full bloom, and may do better than the Gems if we have rain soon and frost does not put in an appearance too heavily. The Premium Gem and other early Peas can be relied upon for a fall crop almost anywhere north if sown in August. Ours would have been over long ago if the weather had been favorable. To my surprise I have never seen here any signs of mildew on fall-sown Peas, while in Maryland it gave us some trouble every fall. We sow these fall Peas in a deep furrow, cover lightly, and work the soil in level as they grow.

We have just sown one crop of Onions, chiefly the Italian varieties. They are sown very thickly on ridges slightly elevated above the surface. These will be transplanted early in February. Northward this sowing may still be done in cold frames, and the transplanting done in March and April. Onion-seed sown here last February in the open ground produced a fine crop, but we think the fall-sowing will give a larger one.

W. F. Massey.

The Crown-bud of Chrysanthemums.

THE proper selection of the crown-bud is of vast importance to all who grow Chrysanthemums for specimen blooms. There is a great deal of doubt, especially among amateurs, regarding its identity. There are, however, certain well-marked characteristics, which, when once recognized, can hardly be mistaken. Although many of our finest blooms are the result of a crown-bud, it is yet an abortion at best, and if left to nature would seldom, if ever, develop. It always appears singly as a terminus to the stem, subtended by two or more lanceolate bracts. In the axils of the leaves, immediately below it, are two or three prominent shoot (never flower) buds, which commence to grow at once. If the bud is not desired, and it sometimes appears in May, as in W. H. Lincoln and Viviani Morel, one of the shoot-buds is allowed to grow, and in a little while the crown dwindles away. The majority of Chrysanthemums show their first crowns from the middle of July to the end of August. According to the experience of several large growers, whom I have visited lately, it is safer to discard all buds which appear before the 5th of August. A good percentage of these will produce what is known as the "second crown" by early September—say between the first and twelfth. A good terminal bud—the last bud to form, and which, by the way, is always subtended by other flower-buds,

often arranged in a cluster—is better than a poor first crown-bud, and generally develops, if not so large, a better-finished flower. Experience alone will show which to take, and it would be well to watch all new varieties in this respect, as well as to note the height they attain on any particular bud. I recently noticed a very even lot of the superb new white variety, Mrs. E. D. Adams, on first crowns, and Rohallion and V. H. Halleck may also be mentioned as being remarkably good. Domination is best on a second crown, while Miss Annie Manda and G. W. Childs are better on either second crown or terminal than on the first. Viviani Morel shows well-formed heads on second crown-buds, but produces flowers of better color and finish on terminal buds. A long list might be made with reference to the value of the different buds, which would be of great service another season.

There is much difference of opinion as to the best time to plant Chrysanthemums. For exhibition blooms all agree that early planting, say by the 15th of June, is best. This gives a longer season of growth and fits the plant to carry a larger bloom. The main objection to early planting is the liability to show crowns too early, say by the end of July, which must be discarded. This means two or more feet of additional height, an inconvenience where head-room is scarce.

There is no doubt that, for commercial purposes, late planting, from July 12th to 20th, is best. Very few of the ordinary first crowns will appear, the buds being about equally divided between second crowns and terminals.

The Chrysanthemum has not reached the zenith of its fame. Its popularity is great, and while it is increasing it is pleasing to notice there is no confusion. Every year growers become more and more critical, and do not hesitate to throw away a variety, no matter how good it may have been, when it is superseded. Although size has hitherto been the aim, refinement is now demanded, and this we see in many of the recent introductions. It is yet too early to speak of all, but in my opinion Mr. John Thorpe's G. W. Childs is the best novelty of 1892. Mr. Hicks Arnold and Mrs. E. D. Adams are flowers of great refinement and beauty, and will be sure to stay. Miss Annie Manda will surely displace Mrs. Alpheus Hardy, at least for commercial purposes, as it grows more freely and is certain to give a good percentage of marketable blooms.

Wellesley, Mass.

T. D. H.

Begonia gracilis.

BEGONIA BICOLOR is the latest addition to the varieties of this interesting and beautiful species, and seems to have been first offered by V. Lemoine & Sons in the autumn of 1891. At present flowering, the plant is very distinct. The leaves are thick and of firm substance, with numerous fine channelings. The color is a dull green with dull white spots, and silvery on the reverse. The stems are thick and succulent. The flowers are, as usual in the type, borne on short axillary peduncles, and are pink and four-petaled. As yet the variety has not sent out any of the thin graceful shoots which, when filled with flowers, help to render the other varieties so attractive. *B. gracilis* is a Mexican species, and I believe the varieties are also natives of that republic. It is usually grown under the name of *B. Martiana*. Mr. C. C. Pringle, in a note in GARDEN AND FOREST, vol. i., p. 7, notes that it grows in a region where the earth freezes and snows fall, and it should be quite hardy. The tubers are round, or sometimes elongated, with smooth white skins. The stems are succulent, and the main one eighteen inches to two feet high. Strong bulbs also throw several shorter ones in addition and numerous axillary ones. The flowers are male and female, rosy pink, and borne on short peduncles. The short branches noted above make very beautiful sprays for cutting, though the species is most useful for the summer decoration of the greenhouse.

Begonias are plants which are readily and rapidly propagated, as a rule, and nature has endowed *B. gracilis* with a full measure of means for its perpetuation. The bulbs when dormant seem to be indifferent to either dryness or moisture and throw off offsets. This plant is an abundant seed-bearer; the stems will strike root, and in the axils of the leaves a plant will bear hundreds of bulblets like mustard-seed, which may be used as seed. Such a plant has many chances for life under the most discouraging environment. The young plants which spring up in the earth on the greenhouse-benches seem usually true to the type, but I have a plant with an elongated bulb bearing flowers which are all female and much darker than the type, and evidently an hybrid.

Begonia grandiflora is evidently a selection with larger flowers. *B. diversifolia* is a smaller-growing kind, with darker

leaves and more numerous branched. *B. racemiflora* is a variety very much like *B. diversifolia*, and, as grown by me, I do not understand the reason for its distinctive name, the habit of flowering not being different from that of the type. Under the name of *B. Martiana pulcherrima*, Messrs. Lemoine offer a variety, said to be a seedling of *B. Martiana grandiflora*, with large deep carmine flowers and red stems and purplish leaves. Messrs. Pitcher & Manda have a form with finely cut and silvery spotted leaves which seems to be still unnamed, and which has not yet been distributed. These plants require positions well up to the glass, or they become somewhat drawn. The culture is the same as that of other summer-flowering tuberous-rooted Begonias.

Elizabeth, N. J.

J. N. Gerard.

The Ornamental Value of Sedges.

I HAVE long thought that Sedges or Carices will some day be considered valuable ornamental plants, and I have begun their cultivation for that purpose. I have just seen an excellent example of their value in the unique botanic garden at the Michigan Agricultural College, where Mr. C. F. Wheeler, who is a most ardent lover of wild plants, and of Sedges in particular, has collected many of our native species. Two distinct types of decorative value are to be seen in these Sedges, one being the free and unique character of clumps shown in the tall-growing and large-spiked forms, the other being the compact and bunched habit of leafy-based species, which are suitable for use in borders. Among the tall species, Mr. Wheeler regards the common *Carex crinita* as one of the best. It grows readily in any low or moist place, as do most of the species, and its tall spreading culms and swinging spikes form a striking object. Other species of similar habit are *C. monile*, *C. utriculata*, *C. lurida* and *C. Tuckermani*, all of which are common in many parts of the country.

Large clumps of any of the strong Carices are unique objects, if grown in a somewhat isolated position, so that the individuality of the species can be seen. Among those species which may be called border Carices, the low broad-leaved kinds are most useful, and these vary so widely in color and habit that excellent effects can be produced by them. Some of them possess a rich glaucous blue color which is very striking. One of the best of the blue ones, especially for sunny positions, is *Carex granularis*, and *C. laxiculmis* is also good. Other excellent native broad-leaved stouling species are *C. plantaginea*, *C. laxiflora*, var. *latifolia*, *C. platyphylla* and *C. Careyana*. All of these succeed in rich loamy soil, and although they usually reach their greatest perfection in half-shady places, if the soil is moist they do well in full sun.

Some Remarkable Plants in San Diego.

To the Editor of GARDEN AND FOREST:

Sir,—The remotest south-western city in the United States has just been celebrating the three hundred and fiftieth anniversary of the discovery of California. Everybody and everything has been laid under contribution to make the best display, so that the celebration from every point of view was successful. Garden art is still young here, and yet horticulture contributed to the decoration of arches, streets and buildings most effectively. Palm-leaves were largely used, and beautiful flowers and choice plants ornamented many of the small gardens surrounding the houses. Among plants worthy of special notice was a *Corypha Australis* with a slender trunk and a huge crown of leaves more than thirty feet high. There were fine specimens of *Seaforthia elegans* twenty to twenty-five feet high, one of them in flower; *Cocos Australis*, in flower also, was most conspicuous for its glaucous foliage; fine fruiting plants of *Erythea edulis*, the Guadalupe Palm, were observed, of which not much is known in the eastern states, and even less in Europe. This is one of the best fan-leaved Palms, and is sure to become a general favorite for its elegance of habit and boldness of foliage. A few specimens of *Erythea armata*, the Blue Palm, were seen. These, though twenty years old, were not very tall, growing more slowly even than *Chamærops humilis*. Besides these there were a numberless host of commoner Palms, such as *Phoenix dactylifera*, *P. reclinata* and *P. Canariensis*, *Washingtonia filifera*, *Chamærops excelsa* and *C. humilis*. These, including the *Seaforthia*, stand full exposure to the blazing sun without damage to their leaves, as happens so often in less hot countries. This is remarkable, and not easy to be accounted for; its cause

must be sought in the telluric and climatic conditions of this privileged country, where one is surprised to see *Poinsettias* growing side by side with *Hollies*, and *Yews* with *Apple-trees*, *German Medlars* and *Raspberries* ripening their fruit next to *Bananas*, *Pineapples* and *Cherimoyers*.

Many interesting plants are to be seen at the far-famed Hotel del Coronado on the narrow peninsula encircling the beautiful bay of San Diego. The spacious court-yard, laid out as a garden not more than six years ago, contains two magnificent specimens of *Cocos plumosa*, thirty to thirty-five feet high; two *Seaforthias* of about twenty feet; a unique specimen of *Kentia Forsteriana* fully fifteen feet high; younger specimens of other Palms, flowering shrubs of many kinds, and a luxuriant growth of climbers, among them the large-flowered and large-leaved *Aristolochia Bataviensis*, *Stephanotis floribunda*, profusely blooming all the year round, but at its best in winter; *Phaseolus Caracolla* and *Ipomœas* and *Bignonias* in variety.

Los Angeles, Cal.

E. F. Franceschi.

Apples Exempt from Scab.

To the Editor of GARDEN AND FOREST:

Sir,—While the blights from fungi have taken nearly every variety of old kinds in our orchards, we are glad to report that those which have a Russian origin are here almost entirely exempt. The thick-leaf characteristic of this class of fruits seems to resist the fungoid diseases, and, with the exception of *Tetofski* and *Zusoff*, have given a full crop of fruits. *Duchess of Oldenburg*, where it carried a heavy crop last year, gave but little fruit this year, but the foliage is very healthy and good. *Alexander*, an old Russian, gave a much better crop than usual. *Red Astrakhan* is all right. *Red Wine* gave us the finest crop we ever had, and they are the handsomest apples I ever saw in a collection of two hundred kinds. This is a new Russian, ripening in September. *Longfield* is probably the most profitable of the new Russians. In eighty varieties, this, on trees four years planted, literally trailed its branches on the ground with nice clean fruit, and the foliage is untarnished. *Yellow Transparent* is also a success, to which there are no objections unless the twig-blight shall injure it farther south; the leaf-blight does not seem to trouble this excellent summer Apple. *Hiberna* is another successful Russian, and I might mention fifty kinds that are successfully withstanding the leaf-blights and scab in this unfavorable year.

We have in Wisconsin a number of seedlings that are carrying their fruit and foliage this year, among these *Wolf River*, which we suppose is a seedling of *Alexander*, also *McMahon*, supposed to be of the same origin. This last is somewhat scabbed in fruit, but the foliage is but little injured. *Avista* is another promising seedling which has not failed a crop in twenty years. We are propagating *Peerless*, one of *Minnesota's* pets, and the foliage is as clean and healthy as that of *Duchess of Oldenburg*. Here at *Janesville*, the *Duchess* has brought to market as many bushels as the best ten varieties of our standard Apples, and it would not be extravagant to say more than all other kinds, but, with the present outlook, *Longfield* will pay better, tree for tree and acre for acre.

This season we found a tree of small white apples which bore two barrels, and was so free from scab, blights and attacks of insects that it attracted our attention, and we exhibited branches with their fruit at our state fair. This tree stands in a pasture where we did not spray at all either for insects or scab, and it may possibly be of value, although the fruit is no larger than *Little Red Romanite*; season October and November; very fine for cooking.

What I should like to urge upon the readers of your paper is to take notes of valuable seedlings and of any variety that pays this off year, and bring such to the notice of their state and local societies and help develop those kinds that are promising. We believe the seedling crosses of Russian Apples with our best native varieties will produce the paying crops of the near future. *Patten's Greening* and *Iowa Beauty* are very promising seedlings along this line; the foliage is perfect and the fruit very desirable.

Janesville, Wis.

George F. Kellogg.

Why do Fruits Drop Prematurely?

To the Editor of GARDEN AND FOREST:

Sir,—Is it not possible that the dropping of the little fruits mentioned in Professor Bailey's article on *Apple Scab*, p. 490, may be partly caused by lack of efficient pollination due to rainy weather at blossoming-time, which interferes with the usual transfer of pollen from flower to flower by insects? In some dwarfed Apples which were examined last summer no

seeds were found, and in others the seeds were few or abortive, indicating lack of efficient pollination. I see no reason why the failure of Apple-fruit to develop may not result from lack of efficient pollination, as was shown to be the case with Grapes in the article on self-pollination, p. 451. It is well known that pollination from an uncongenial source, while not resulting in well-developed specimens of fruit, still may incite the growth of little fruits, which soon drop away or persist in an abortive or dwarfed condition. It may be true that the dropping of the little apples was not due to lack of efficient pollination, yet there are reasons why this may well be considered as one of possible causes. It was shown by M. B. Waite, in a paper presented at the Rochester meeting of the American Association for the Advancement of Science that certain varieties of Pear are incapable of fertilizing themselves. A few tentative experiments made by Dr. Halsted,* Professor D. G. Fairchild† and the writer indicate that excessive rainfall at blossoming-time may seriously interfere with the setting of fruit in the case of Apples and Pears, and, in a less degree, of Grapes. In many orchards last spring, however, the rainy weather did not prevent the trees from setting full of fruit, but in a short time most of it fell off. Some experiments of the writer in cross-fertilization and self-fertilization of the Apple lead him to suspect, as suggested by Mr. Waite and as proven to be the case with Grape and Pear, that certain varieties of this fruit also can fertilize their own blossoms only in an imperfect way.

S. A. Beach.

Warm Water for Tender Nymphæas.

To the Editor of GARDEN AND FOREST:

Sir,—I agree fully with Mr. James Brydon when he says "the best Nymphæas are grown in deep water," instead of a depth of six or eight inches as sometimes practiced. The most difficult problem to solve, however, is how best to heat the water to a depth of two to three feet below the surface. I have maintained for some years ponds for the cultivation of tender Water Lilies and *Victoria Regia*, using the ordinary system of hot-water heating by taking the supply to the heater from the bottom of the pond and returning heated water about eighteen inches below the surface at the opposite side of the pond. The plan is a fair one, if no better means can be devised, but the objection is that the hot water ascends to the surface immediately on being discharged and the temperature of the water one foot below the surface is generally very much below that at the surface.

Now I have a plan, new to me, that I propose to try next season. A large steam boiler used for power is within three hundred feet and it is proposed to take a steam pipe through a small brick conduit laid underground, the pipe being well covered with a good non-conducting material and then the bricks laid in cement to cover. Coils of one-inch galvanized iron pipe will be laid on the bottom of the pond, or rather the pipe will be laid round in increasing circles, and the condensed steam will be taken away by a pipe out of sight or it can be utilized to raise the water, or make up any leakage or evaporation. A large bulb of mercury is to be arranged so that by expansion or contraction the steam will be turned on or off. The pond is forty-two feet in diameter and three feet six inches deep, but it is confidently believed that by having the source of heat at the bottom in the form of hot steam pipes the problem will be solved. If any one who may read the views here expressed knows any reason why the plan is not a good one I should be pleased to hear it.

Northampton, Mass.

W. W. Lee.

A Unique Chrysanthemum Show.

To the Editor of GARDEN AND FOREST:

Sir,—Los Angeles has, in the last six or seven years, won a reputation for flower-fêtes that can scarcely be excelled in magnitude or beauty anywhere in the country. In April of each year the Flower Festival Society, a band of philanthropic women, gives a fête which fills a large pavilion. Later, the professional and amateur gardeners of southern California have their annual exhibit, and for three years the Chrysanthemum has been exhibited on a large scale by the women of one of the churches.

The two Chrysanthemum exhibits previously made were in spacious halls. Last spring a plot of unoccupied ground ad-

joining the church was secured. This space, 140 by 165 feet, was placed in the care of a Japanese gardener, who laid it out in beds and winding walks, with reservations for a dozen booths, and planted it with over 10,000 choice Chrysanthemums. An immense cloth tent was placed over it, and here, during the fête, was a scene pronounced by many visitors to be the most beautiful they had ever beheld, even in this land of wonderful flower-shows.

Directly opposite the entrance a miniature mountain-range extended, its sides covered with verdure, and its cañons filled with flowers, while on the summit pure white blossoms were massed. Passing around this sierra one came upon a tiny lake bearing rare aquatic plants upon its bosom. The pretty booths were entwined with climbers, mostly Sweet Peas in various colors and Smilax. The smooth broad walks, winding as in a maze, separated gorgeous beds of Chrysanthemums, some in shaded colors, others of a single hue. Nearly 300 varieties were represented in the garden. From the frame-work supporting the tent were suspended flags and streamers of all descriptions such as are used in Japan. The pillars were covered with a luxuriant growth of the Moonflower-vine in blossom, and the surrounding fence was concealed and transformed into a thing of beauty by clinging Morning-glories. At one side of the garden was a Japanese hut, made entirely of bamboo, and thatched with grasses in the style of that country. Outside its door were bamboo-tables holding tea-services in Japanese ware, and here a cup of the genuine oriental article, served with joss-sticks, could be had.

Besides the thousands of Chrysanthemums growing in the ground, the property of the ladies, there were many fine specimens in pots sent by florists in competition for the prizes offered. There were also about 2,000 Aster-plants, and many Dahlias, Cosmos and Carnations. All the plants belonging to the church were for sale at the close of the exhibition.

This show, without doubt the most extensive outdoor exhibit of Chrysanthemums ever made in this country, it is pleasant to know was a financial success as well as a means of pleasure and instruction for the public.

Los Angeles, Cal.

Periodical Literature.

An interesting article in the October number of *The Atlantic* is Professor N. S. Shaler's "Betterment of our Highways." We may not fully endorse his opening remark that "Perhaps the best of the many measures which may be applied to modern states to determine the degree of advancement to which they have attained may be found in the condition of their common roads." For this naturally leads to his conclusion that, "judged by the standard of our local ways, America as a whole must be regarded as the least advanced of all the countries which are commonly classed as civilized." But Italy, for example, has better common roads than ours; yet if "advanced" is taken in any really general sense, few persons will assert that Italy is more advanced than the United States. Professor Shaler acknowledges, indeed, to a fact which has already often been pointed out—that the newly born railway was an extremely detrimental influence upon the extension of good common roads in this country. But we think he might have laid some emphasis upon this fact as mitigating our still-too-evident sins in the matter of common roads, and entitling us to consider ourselves more civilized than some other nations whose roads are better.

However, this is a minor point. For the most part what Professor Shaler says is so true, and has so long been true, that it is a disgrace as well as a wonder that any one should have to say it again to-day. But it must be said to-day and to-morrow and the day after to-morrow, by many voices as often as they have opportunity, if the public at large is to be awakened to a vivid realization of an evil which means an active concerted effort for its abolition. Therefore, Professor Shaler's article is very welcome as one of the clearest and best expositions of the subject that we yet have seen. He does not waste time in describing how bad most of our roads are; he devotes his attention chiefly to showing how they may be improved. His explanation of the extreme difficulty of good road-making—which means, not the persistent use of one consistent scheme, but the perpetual adaptation of sound fundamental ideas to very different local conditions—ought to show our legislators and our educators how necessary is thorough training in the art of road-making if good roads are to come in all parts of our country. Nothing could be more evidently true, yet nothing could more insistently need saying, than that "the first step toward our new dispensation is to persuade our greater schools to undertake the systematic education of road-

* "Influence of Rainfall at Blooming-time upon Subsequent Fruitfulness," p. 230, *Annual Report N. Y. Exper. Station, 1890.*

† "The Effect of Rainfall upon Pollination." Paper presented before the last meeting of the American Horticultural Society by D. G. Fairchild and S. A. Beach.

masters, giving to the task the same care which they devote to the preparation of young men for railway or hydraulic engineering. . . . The Lawrence Scientific School of Harvard University has already arranged for the services of an instructor in this department, who will devote all his teaching to matters connected with road-construction. . . . If a dozen of our engineering schools in different parts of the country will provide similar systematic and continuous instruction, we may hope, in the course of four or five years, to graduate trained road-masters who are well informed in the science and art of their profession."

Notes.

The Prussian Academy of Sciences recently voted a grant of 2,000 marks to Professor P. Ascherson, to enable him to issue a new edition of Koch's *Synopsis floræ Germaniæ*.

It is reported from St. Petersburg that the beautiful gardens on the island of Fontanka, in the river Neva, were totally destroyed during a terrible storm which occurred on the night of September 23d, when the stream rose to a height of six feet above its normal level.

Among the special prizes at the Chrysanthemum Show, to be held next week in Madison Square Garden, New York, is the GARDEN AND FOREST Cup, valued at fifty dollars, and offered by the publishers of this paper for the best vase of cut Chrysanthemums containing six blooms of any one variety.

Of hybrid perpetual Roses, Mrs. John Laing was exhibited oftener this year at English exhibitions than any other variety, and it is only excelled by Madame Gabriel Luizet and La France in the number of times it has been staged during the last three years. Among the Tea and Noisette Roses, The Bride, which is a nearly white sport from Catharine Mermet and of American origin, was shown the oftenest—that is, forty-five times.

In the famous old gardens of Syon House the Lebanon Cedars are noted for the cleanness, the length and size of their trunks rather than for the great sweep of boughs. Trees with branches which spread 100 feet are not uncommon, however, nor are trunks rare which are fifteen feet in circumference. There are many striking specimens of *Taxodium distichum* in this garden over 100 feet in height and throwing up knees two or three feet high over a circuit 100 feet across on the turf.

Apart from its beautiful flowers, graceful form, the delicate texture of its bark and ample foliage during the summer, the Virgilia, or Yellow-wood (*Cladrastus lutea*), deserves to be noticed as taking rank among the most beautiful of our native trees for its autumn coloring. While the majority of trees whose dead leaves do not cling to the branches all the winter are entirely stripped, the Yellow-wood is still well clothed with foliage of a clear yellow which is especially bright when the sun shines on it.

On account of the graceful way in which its snowballs are tossed in the air, the old-fashioned *Viburnum opulus* is superior to the newer Japanese species *V. plicatum*. The foliage of the latter, however, is not nearly so liable to be crumpled up by insects, and it has the additional advantage that its foliage turns in autumn to a deep and rich color, which is altogether indescribable in words, but which has been called a crimson-bronze. The leaves, too, cling to the shrub very late, so that this rich coloring appears at a time when it is highly appreciated.

In the diary of the late Professor J. W. Bailey, some extracts from which were recently published in the *Bulletin of the Torrey Botanical Club*, it is related, on the authority of Dr. Torrey, that Professor Lindley's well-known *Outlines of the First Principles of Botany* was wholly written on journeys to and from his residence, about six miles from London. "When the stage stopped at an inn Lindley would write on a scrap of paper a sentence or two of the work, using his hat as a desk, and this was but one instance of the constant devotion and industry of the Professor."

The *Gardeners' Chronicle* quotes from one of the essays of Mr. William Paul, which have been lately collected into a volume, the following sentence: "It would be commercially unwise to attempt to raise Hyacinths against such skillful gardeners as the Dutch. We can buy and sell cheaper than we produce." To this the *Chronicle* adds the comment that, while it is true as a general statement, experience at Kew for two or three years tends in the opposite direction, and, indeed, it is a fact that bulbs have been cultivated successfully in the

sand-hills of Sandwich. We may add, that experiments in this country show that more than one of the so-called Dutch bulbs can be grown with profit here.

Mr. Thomas Calhoun, of Wilson County, Tennessee, was one of a committee appointed in 1847 to select the grounds for a camp-meeting and the site for the audience-shed. He carried with him a Sycamore handspike, which he drove into the earth at the spot chosen for the pulpit. The shed was soon erected but the stake was not disturbed, and in time it put out shoots and leaves. Mr. Calhoun was about forty-five years old when he drove in the stake, and he is living yet to see it after it has developed into a tall Sycamore, twenty-two inches in diameter and as straight as a stove-pipe.

It is an unusual season when Cannas are blooming out-of-doors in the last days of October, and therefore it is not fair to expect that the earlier kinds of hardy Chrysanthemums will always do as well out-of-doors as they are doing now. At the same time there are few years when we have not many bright warm days in October, so that if hardy Chrysanthemums are covered up for a few bitter nights we may generally expect that they will give good bloom until November. Of course, exhibition blooms can never be grown out-of-doors, but with a proper selection of varieties we can have sheltered spots in our out-of-door gardens gay with the crimson and yellow and white of the hardy Pompons and Chinese varieties.

During the second week of October there could be seen in this city near the Worth Monument, on the Broadway side of the triangle which is encircled by Horse-chestnut trees, one specimen which had done its best to decorate in honor of Columbus. Like most of our city Horse-chestnuts, it had long been almost leafless, clothed only by a few gray and shrunken shreds of foliage. But before the other festivities began it threw out from the ends of several of its branches tufts of fresh bright light green leaves, and even some panicles of blossoms which, while not so large and full as those of its spring-time, had a very odd effect against the background of the sparse withered leaves. The fresh leaves and flowers together looked as if they had been tied to the trees instead of growing there in defiance of the seasons.

One of the most attractive objects in Ventura, California, according to the *The Unit*, which is published in that town, is a hedge of Heliotrope two hundred feet long, facing the street, and in the gardens of Mrs. Theodosia B. Shepherd. The walk is three feet below the garden-level, and on the banks above, wires stretched upon low posts support the plants, which now droop down to the walk and stand six feet above it covered with fragrant masses of flowers. The plants were set out five years ago, and all the year their beauty and perfume attract not only the birds and bees, but children passing by fill both hands, and gentlemen and ladies catch a spray for a boutonniere or a corsage-bouquet, for Mrs. Shepherd says the Heliotropes belong to the town. In the last week of September the branches were trimmed and the seed gathered. Three men were kept busy for two days cutting, raking, sweeping and sifting. The trimmings were carried away by the wagon-load, and twenty-five pounds of good, firm seed harvested, and yet, in a fortnight, the hedge will be prettier than ever. It requires trimming three or four times a year.

In speaking of plants which are in danger of extermination, M. V. Brandicourte, Librarian of the Linnæan Society of the North of France, writes in the *Journal of Horticulture* that one of the most graceful species of Eucalyptus, *E. Alpina*, formerly abundant in Mount William, in Australia, would now be unknown had not Baron von Mueller planted the specimen in the Botanical Garden at Melbourne. *Psiadia rotundifolia*, a tree belonging to the Compositæ, some twenty feet high, with heavy naked branches and small Aster-like flowers, was once abundant in St. Helena. Man and goats have played such havoc with the forests of that island that this species would be reduced to a single individual but for the fact that it has been cultivated at Kew. From the Department of Sonne, in France, some fifty species have already disappeared, or are tending to disappear, those most menaced being plants sought by amateurs or horticulturists on account of their gracefulness or the brightness of their flowers, and those which are taken by botanists, who sack everything that is rare. Foreign botanists have extirpated even the last living representative of the dwarf Palm (*Chamærops humilis*), which formerly grew in the vicinity of Nice, and an interesting Orchid, *Spiranthes Romanzoviana*, with a white and exquisitely fragrant flower, has apparently disappeared from the small meadow on the borders of Bantry Bay, in the south of Ireland, which was its only known station.

Quercus densiflora.

THE Tan Bark Oak, as *Quercus densiflora* is usually called in California, is morphologically the most remarkable of all the North American Oaks, and in some respects is almost as much of a Chestnut as it is of an Oak, although its fruit is a true acorn. The inflorescence resembles that of the Chestnut, and consists of a cluster of long, erect aments, pistillate at the base and staminate above, or entirely staminate, and particularly conspicuous from the slender filaments many times longer than the minute anthers. From those of the Chestnut, however, the female flowers differ in being solitary, and not clustered in the involucre which develops into the cup of the acorn. This tree is particularly interesting, therefore, as showing the near relationship between the Oak and the Chestnut, while to the student of plant-archæology and of the laws which govern the distribution of forms of plant-life over the surface of the earth, it is of special interest. No other tree in America or Europe resembles it, but in eastern and southern Asia there is a whole group of Oaks so similar in the structure of their flowers to this solitary inhabitant of the New World that it is possible to suppose that the Californian and the Asiatic trees possessed, not very long ago, a common ancestor from which the two lines, slightly differentiated in structure and now widely separated geographically, have come down. The relationship is all the more remarkable, because it is in the flora of eastern America, and not in that of the western part of this continent, that we are accustomed to find eastern Asiatic types, and the peculiar trees of our Pacific forests have few prototypes on the opposite shores of that ocean.

The Tan Bark Oak is one of the handsomest and most useful Oaks of North America. Large specimens, which are sometimes a hundred feet tall, develop a broadly conic to oblong head of unusual regularity and beauty. Under the shadow or on the borders of the forests of Redwood, the favorite situation of this tree, it is forced upward in

search of light, and then forms a more or less spire-like top, but in open situations where light and space abound, the branches spread out horizontally and form the broad head which makes some individuals of this tree as handsome and symmetrical almost as it is possible for any Oak-tree to become. The leaves are persistent through the year, large, leathery, and lustrous, in shape and size not inferior to those of a vigorous Chestnut-tree, but much thicker, and while young covered on the lower surface with pale tomentum which, in disappearing, leaves them pale and smooth. Like all California Oaks, individuals of *Quercus densiflora* differ remarkably when subjected to different conditions of climate and soil. Sometimes they are tall and stately trees, and sometimes little bushes with slender stems only a few feet high. Sometimes the leaves are six or seven inches long, sharply and boldly toothed, and very thick; on other individuals they are thin, entire or nearly so, and barely an inch and a half long. The fruit, however, with its beautiful shallow cups, silky-tomentose on the inner surface and covered with long linear spreading and recurved scales, does not vary except in size, so that when the trees are in flower or are bearing fruit, it is easy to distinguish them in spite of the uncertain characters afforded by the foliage.

The wood of the Tan Bark Oak is hard and heavy; it is too porous, however, for casks, and, like that of all the California Oaks, is too brittle to be of much use for the purposes for which Oak-timber is mostly esteemed, although it makes good fuel. The great value of the tree is in the character of its bark; this is extremely rich in tannin, and leather made from the wood is of excellent quality. The bark of no other tree of the Pacific coast is so esteemed by tanners, and for years its systematic destruction has been going on in all the region it inhabits. This, fortunately, is of considerable extent, as the Tan Bark Oak is scattered over the coast-ranges from the valley of the Yumqua River, in Oregon, to the Santa Lucia Mountains, in southern California. Unlike some of our eastern Oaks, however, it never forms a large part of the forest, and although it was by no means a rare tree thirty years ago, it was nowhere very abundant. Like other Oaks, it reproduces itself freely if fire and browsing animals do not destroy the young plants too often, but natural reproduction is not keeping pace with the annual destruction of the old trees, and unless conditions of forest-management in California are radically changed, in the course of a few years the Tan Bark Oak, like several other California trees, must become extremely rare, and California tanners will have to depend on the Hemlock-forests of the far north, or on the bark of Australian Acacia-trees, raised in the south, to supply their vats. This is a state of affairs which they should not contemplate with equanimity, as it will mean that they will not be able to compete advantageously with the product of eastern tanneries.

The illustration on page 523 of this issue displays a fine specimen of *Quercus densiflora*, grown on the borders of the forest, in the neighborhood of the Bay of San Francisco. For the photograph from which it has been made, our thanks are extended to Mrs. T. S. Brandegee, of San Francisco, who kindly furnished it for publication.

The White Mountain Forests.

IN the very first number of the first volume of this journal Francis Parkman made a plea for the preservation of the forests of the White Mountains because of their importance as elements of the scenery which makes that region so attractive to summer tourists, and so profitable, therefore, to the state of New Hampshire. This value is just as real and tangible as is the modifying power of a tree-covered mountain-slope over the agriculture and manufactures and general health of the people who live in the plains below and receive their water from fountains above. It is a value which can be estimated in dollars and cents as truly as can the wood-products which pass into economic

use through the saw-mills. The sweeping away of these forests means irreparable loss to the people of New Hampshire, and the desolation of its scenery will bring more serious impoverishment to the state than the drying up of its water-sources and the extinction of its timber-supply.

Since these woodlands belong to private individuals there is no legal means for arresting the destruction of the mountain forests and the calamities which will surely follow. The only way in which this scenery and the revenue which comes to the state from it can be perpetuated seems to be some reassertion by the state through legislative enactment of its original control over these forests. We are well aware of the obstacles in the way of a proceeding which appears so unusual, although founded on principles which are accepted without question as the basis of many other laws and customs. We do not assume, therefore, to urge upon the people of New Hampshire the adoption of this policy, but we are sincerely gratified to learn that a movement in favor of this exercise of the right of eminent domain has been started in New Hampshire. This makes a definite issue, a specific question to which there is an affirmative and negative side. There is no dispute about the present facts of the case. If there is no check put upon the forest-destruction in that state, the White Mountain region as a summer resort is doomed more certainly than are the manufacturing interests along the Merrimac. It is high time, therefore, that the people of New Hampshire should face the situation, and make up their minds what to do about it.

Mr. J. B. Harrison, the Secretary of the Forest Commission, is in the field, and has agreed to speak anywhere in the state where a meeting can be arranged. All the intelligence of New Hampshire ought to be enlisted in a discussion of such moment. There is no village or school district in the state which would not find it profitable to organize a meeting to consider the responsibility of the people of the state for the forests of the state. Every newspaper should help to kindle popular interest in the subject. Great changes are in progress, and wise men will adjust themselves to coming conditions. If, as it would seem from articles which have recently appeared in New England papers, the hotel-keepers and owners of factories—that is, the men most immediately concerned in this movement—are apathetic, it is time that the public spirit of the whole people should be aroused. Nothing but good can possibly come from a clear presentation of the truth and a dispassionate argument upon the merits of the proposed policy.

Grottoes in France.

AT a reunion of the Fine Arts societies of the various departments of France, held in Paris during the past summer, Monsieur de Montaiglon spoke of those grottoes built with shells and irregular ornamental stones, which were so much in vogue for the ornamentation of gardens from the beginning of the sixteenth to the end of the eighteenth century, and the humble successors of which are found in the rockeries of the modern garden. He cited especially the great grotto of the palace at Fontainebleau, made in the time of François I., those which Palissy erected for the Duc de Montmorenci, and which, if ever finished, were probably transported, the one to the Château d'Ecouen, destroyed in the French Revolution, and the other to Chantilly; the one which was built in the Tuileries gardens, in Paris, and the one at the Château d'Anet, the materials of which must have been very diverse and valuable, as when this place was likewise destroyed during the Revolution, they were preserved and formed the beginning of the national Museum of Natural History.

Furthermore, among historical grottoes, the speaker named one constructed by the Cardinal of Lorraine at the Château de Meudon, which was removed by the son of Louis XIV. to make room for the construction of a new building; those at St. Germain belonging to the palace

built by Henry IV.; the one near the Menagerie at Versailles, and, also at Versailles, the one called the "Baths of Thetis," constructed, it is said, to receive the groups which afterward were used to ornament the "Baths of Apollo"; and those connected with the private apartments of the king, of Mademoiselle de La Vallière and of Madame de Montespan—all made at the same time and each costing the same amount of money. Fouquet had a conspicuous grotto on his famous estate at Vaux, made familiar by the descriptions in Dumas' *Vicomte de Bragelonne*; Charles Lebrun, the painter, had one at his country-house, and so did Charles Perrault, the architect, at Méry-sur-Orge, and this last still exists in excellent preservation.

These are by no means all the grottoes which once were famous in France, but the list is long enough to show how fashionable they were. And their history and remains are of especial interest, because, from the love of this rock and shell work and of the irregularly decorative forms it implies, it eventually affected French taste in general, and brought about a revolution, not only in decorative but also in architectural art. Every one knows the architectural term "Rococo," and the nature of the art it characterizes. But perhaps it is not so generally known that the word comes from *rocaille* (rock-work), and that the form of art it characterizes sprang from the same source. When this fact is known, however, it is easily read in all the work of the age of Louis XV., where unsymmetrical line, and masses, and flowing ornaments of shell-like or sharply pointed, but always irregular shape, mark every kind of manufactured object, from house-fronts, doors, wall-decorations and wrought-iron gates and railings to furniture, table-china and silver, laces, dress-materials, jewelry and every minor article upon which the designer of forms and patterns worked. This is probably the only instance in which a general and radical revolution in taste, affecting art from its highest to its humblest manifestations, originated in a special development of taste as regards the ornamentation of gardens.

Are American Varieties of Fruits Best Adapted to American Conditions?

THE following paper was read by Professor L. H. Bailey before the American Horticultural Society at its meeting last month in Chicago:

Fruit-growers assume that the varieties which have originated in this country are better adapted to our soil, climate and market than those imported from other countries. While the presumption favors this idea, the proposition demands investigation, and, if true, it should be capable of proof. It is obvious that domestic varieties are best adapted to the demands of our markets, because those seedlings which most nearly meet these demands have been selected and propagated. The commercial ideals are definite and easily satisfied, and we need not longer consider them here. But the adaptations to all those various conditions and phenomena which we collectively designate as climate, are obscure, and they have not been carefully studied; and this relationship of American varieties to American climate, so far as it concerns some of the general adaptations of our fruits, is the particular subject of this paper.

We can draw some useful conclusions from a comparison of our native flora with that of Europe, whence most of our foreign fruits are derived. With the exception of some arctic and sub-arctic species, the plants of North America are singularly distinct from the European plants, although much like them. There are few species which are common to both continents. Most of the plants which were once thought to be the same in both continents are now separated by botanists, and I am convinced that this separation should proceed to nearly, if not quite all, the remaining supposed identical species of the temperate latitudes. The more closely we study these species the greater the differences of habit and distribution appear to be. All this proves that, while the European and North American floras had a common origin in circumpolar regions, the present floras of the two continents have diverged, until nearly or quite all the specific types in the central and southern areas are dissimilar. This dissimilarity has been brought about by the action of environments—largely of climate—in the two continents. In other words, the habitual dissimilarity of the floras

proves that the climatic environments are so different that identical species rarely thrive in both. And this fact lends plausibility to the statement that horticultural varieties, which differ from species only in degree and not in kind, must constantly tend to diverge in the two countries.

The dissimilarity of European and American congeneric species is well illustrated in some of our fruits. Thus our cultivated Raspberries, Blackberries, Gooseberries and Grapes are American species, and the profitable cultivation of these kinds of fruits did not begin until we gave up our endeavors to grow the European species. The case of the Red Raspberries is particularly instructive because the European and American species are so much alike that botanists have never been satisfied that they are distinct; but all berry-growers know that the European varieties will not succeed as market berries in this country. This superiority of the American small fruits and grapes is not due to any greater excellence in quality or appearance in these fruits; on the contrary, they are commonly inferior in these points, for they have not yet had a long enough history to bring them to a high degree of perfection. Their success is due to their perfect adaptation to their surroundings, as an ability to withstand our climate or the attacks of insects and fungi. The capability to withstand or repel attacks is well shown in the Grapes, which resist downy mildew and phylloxera better than the European varieties, and in the American Gooseberry, which does not suffer seriously from the mildew. The European Plums are also subject to difficulties which the native species, now coming into prominent cultivation, more or less avoid. What is true of a comparison of the European and eastern American floras appears to be true, in varying degrees, of comparisons of other floras with our own, all of which shows that the horticulture of eastern and central North America must constantly tend to differentiate itself from that of all other countries.

If these general conclusions are well founded, we should even now be able to find some corroboration of them in a study of our varieties of fruits, for the literature of our horticulture covers three-fourths of a century, and evolution aided by cultivation is much more rapid than under wholly natural conditions. Among the fruits which have been brought from Europe the Apple has been longest cultivated in this country, and it thrives over the widest range, and we should be able to draw some valuable lessons from its behavior. The first American work on pomology was William Coxe's, published in 1817. In this work is given a list of "one hundred kinds of the most estimable Apples cultivated in our country." The list contains one hundred and one kinds, of which only about a half-dozen are now popular, and only one, the Rhode Island Greening, can be classed as a general market fruit. The geographical origins of eighty-nine of these varieties are determinable, of which number thirty-two, or thirty-six per cent., are of European origin, and fifty-seven, or sixty-four per cent., are American. The first edition of Downing, 1845, describes one hundred and ninety varieties of Apples, one hundred and eighty of which have known origins. Of these one hundred and eighty kinds, eighty-seven, or about forty-eight per cent., are European, and ninety-three, or fifty-two per cent., are American. Between 1817 and 1845, therefore, there was apparently a gain in the introduction of European Apples over the American; but this need excite no surprise when we consider that those were the pioneer and formative days of American pomology, when great discrimination in varieties was not practiced, and when Europe was the most prolific source of new varieties.

In the second edition of Downing, 1872, we find a decided change. There are descriptions of 1,823 varieties of Apples, and the origins are fairly well determined of 1,326 of them. Of this number 464, or 35 per cent., are European, and 862, or 65 per cent., are American; and these figures undoubtedly give undue advantage to the European Apples, because of the 497 varieties unaccounted for, I should judge that fully three-fourths are American. In the twenty-seven years between the first and second editions of Downing, therefore, there was a remarkable falling off in percentage of Apples of European origin and a corresponding increase in American varieties. It would not be safe to say, however, that all of this loss in European varieties is due to lack of adaptation of these varieties to our climate and other environments. Fashion or the desire to patronize domestic productions may have influenced this result, yet it is not probable that either of these causes could have defeated a profitable variety. But there is another and more important aspect of the question, and that is the fact that probably over three-fourths of the prominent Apples belong to the American part, which comprises 65 per cent. of the list; and of the popular market Apples a still greater per-

centage is to be found among the Americans. In this connection we may study with profit the Michigan Fruit Catalogue (1888), prepared by T. T. Lyon, which rates all prominent varieties for Michigan in three categories—dessert, culinary and market—upon a scale of ten. This catalogue contains 219 varieties of Apples. Of these thirty-eight are rated nine and ten for dessert, of which two are known to be of European origin and three more are supposed to have come from that country—that is, somewhat over an eighth of the dessert apples of Michigan are of probable European origin, the remainder being domestic varieties. Mr. Lyon admits nineteen varieties to the rank of nine and ten for market, of which two—Duchess of Oldenburgh and Red Astrakhan—are Russian, and another is perhaps of European origin. Less than one-sixth of the Michigan market apples, therefore, are of Old World origin, and one of these—the Duchess—is of recent introduction as a market apple. Of the nine Crab-apples admitted by Mr. Lyon, all but the comparatively unimportant Red Siberian are of American origin.

The Pear affords an interesting study in this connection, for it is a fruit which has been highly cultivated and developed in Europe, but has received only indifferent attention in this country, so far as the production of varieties is concerned. Coxe, in 1817, described sixty-five Pears as grown in this country, of which only four, or less than one-sixteenth, were American in origin. Of the whole list, only the Madelaine is popular now. In 1845 Downing described 239 kinds, 192 of which, or 80 per cent., were European, the remainder being American. In 1872 the Downings admitted 995 varieties, of which 954 have a known geographical origin. Of these, 708 varieties, or seventy-four per cent., are foreign. There has, therefore, been a gradual increase in the percentages of domestic varieties from the beginning, although the foreign kinds are still predominant. In Mr. Lyon's Fruit Catalogue twenty-one Pears are admitted as nine and ten for dessert, of which seven, or just one-third, are American; and exactly the same ratio holds in the twelve varieties standing nine and ten for market. All these facts are indications that even in Pears the American varieties are prominent and are increasing in number, and they suggest the possibility that European varieties may eventually practically disappear from our horticulture.

What is true of Apples and Pears appears to be true also of other fruits. Of the seventy Peaches which Mr. Lyon catalogues, only five are foreign among those rating nine and ten for dessert and market, and of this number only one—the Rivers—is prominent. Next to the Pear, the common Plum is the most peculiarly European of any fruit of eastern and central United States, yet of the fourteen varieties admitted by Mr. Lyon as nine and ten for dessert, one-half are American, and of the six market sorts, four are American. It is interesting to note, also, that the region of adaptation of the common Plum is not large, and that the varieties of the native species are evidently destined to cover a very wide range of our southern and interior territory.

If any conclusion can be drawn from all the foregoing figures and remarks, it is to the effect that, as a rule, American varieties are best adapted to American conditions, notwithstanding the fact that there are some foreign varieties which thrive over large areas of this country.

The question of the adaptations of the Russian fruits to this country at once arises, and this brings up a still broader question, the adaptability of our own eastern fruits to the great interior basin. On a former occasion* I made an examination of the reasons for the premature failure of Apple-orchards in the prairie states, and I satisfied myself that much of this failure is due to the transplanting of New England and New York varieties to those regions. Every fruit-grower must have been impressed with the fact that the Apples of these prairie states are rapidly assuming a different character from those of the east, and the leading varieties in the two sections are even now distinct. The dissimilarity between these great regions in climatic conditions is also well illustrated in the floras, for there is a marked tendency for the specific types of the east to stop at the borders of the prairies. In other words, we have floras characteristic of the prairies and plains. Even the Wild Crab (*Pyrus coronaria*) of the eastern states does not occur in the prairie regions, so far as I know, being there represented by its congener, *P. ioensis*, a well-marked species. More than all this, we know that it is absolutely impossible to grow our common eastern fruits in the cold north-west. Our interior regions must, therefore, be considered apart from the older states, and when we once understand this fact thoroughly much of the prejudice against Russian fruits must disappear.

* *On the Longevity of Apple-trees.* Kans. Hort. Soc., 1890.

The situation is simply this: the north-west must have an unusually hardy class of fruits, and any type of fruit which will grow there should be encouraged. The Russian is simply one of these types, the Siberian and native Crabs being others. But, inasmuch as the Russian type is the most highly developed of them, it follows that quick results are to be expected from it. If the Russian Apples and the Crabs are more or less adapted to the north-west, I feel sure that American seedlings of them will be still better adapted to those conditions, as a whole, and this must be the opinion of many of the fruit-growers of the north-west, else the talk about promising seedlings of Duchess and other families is meaningless. Already the McMahan, Wolf River, Pewaukee, North-western Greening and others are great blessings to the north-west. I look for the time when the present imported fruits and Crabs will be superseded by their own progeny in the same way that the lists of Coxe and other early writers have been supplanted. Already the tide has set in which shall submerge them. I therefore regard the Russian importations as of immeasurable benefit to our horticulture, but I look upon them as a means rather than as an end. The history of our horticulture everywhere emphasizes the probability of a secondary and more important outcome.

The conclusion of the whole matter, as it now lies in my mind, is this: American fruits constantly tend to diverge from the foreign types, which were their parents, and they are, as a rule, better adapted to our environments than foreign varieties are. In less than a century we have departed widely from the imported varieties which gave us a start. At the expiration of another century we should stand upon a basis which is nearly, if not wholly, American.

Hard Times in West Virginia.

RETURNING to Rose Brake, after an absence of nearly two months, the home-grounds were found parched and browned by the worst drought ever known here. All vegetation was languishing, the foliage of the trees shriveled and scorched, the color of the leaves dull and faded. Even the Virginia Creeper, which in October waves its scarlet drapery from the trunks and tops of the tallest trees, was a sober brownish crimson.

Coming from the hills and mountains about the Delaware Water Gap, where timely showers had kept the grass fresh and luxuriant, and where the trees were already beginning to glow with autumnal color, we found the desolation in the valley of Virginia all the more apparent by contrast. In the home-grounds the evergreens had suffered the most, and many had perished outright. A good watering followed by heavy mulching has, in past summers, tided many nurslings over a parching drought; but this year, with dry cisterns and the absence of the care-taker, such treatment was impracticable. Few deciduous trees or shrubs have succumbed to the heat, but nearly all fall-blooming plants have found it hard enough to hold their own without flowering, and few blossoms cheered the garden-beds. The sunny bloom of the brave Marigolds and *Corchoruses* nodded a welcome to the visitor, but the *Hydrangea*-heads had withered on their stems, and the Japanese *Anemones* were nearly dead.

A few berries ornament the bushes here and there, and the Witch Hazel has put out its yellow fringes amid shriveled leaves. A plant sent to me as *Elæagnus longipes*, and described as a "shrub or small tree that ripens its berries in July," is now covered with fruit, both green and red, and has capriciously waited for frost before commencing to ripen. The berries have a pleasantly acid and slightly mucilaginous taste. We have not yet tried them as a substitute for cranberry-sauce, for which purpose they have been recommended. They are so pretty on the tree, densely scattered along the limbs, and so quaintly marked with fine gray dots over the surface of lucent green or red, that it seems a pity to pick them for any purpose. The birds trouble them very little, perhaps because birds do not care to try food-experiments; but I fear that when they discover their delicious qualities they will leave very few for us. [The plant is not *Elæagnus longipes*.—ED.]

Thunberg's Barberry has turned crimson, and the berries are a brilliant scarlet. Some Thorn-trees are a vivid mass of fruit, and *Cotoneasters* are covered with balls, which look like tiny apples, yellow and red.

In one part of the grove we have planted trees and shrubs with a special view to their fall aspect, and these we are now watching with special interest. Here are *Enkianthus Japonica*, *Parrotia Persica*, and a few other rarities, which are at their

best in October; also a fine young Scarlet Oak, Scarlet and Sugar Maples, Sour Gums, *Kolreuteria*, Liquid Amber, Sumachs, *Virgilia*, and many shrubs. Of this group, only the Sour Gums have been as brilliant as usual.

Our pretty little *Erica carnea*, which is planted in a hollow, is as fresh-looking as it was in May, and has bloomed steadily since the end of June without watering. The same may be said of *Abelia rupestris*, a most beautiful and interesting little evergreen. *Aster oblongifolius*, still covered with buds, has begun to expand its large blue ray-flowers. This is one of the handsomest of Asters, and withstands drought as well as *Portulacas* do; hundreds are blooming, undeterred by frosty nights.

Rose Brake, W. Va.

Danske Dandridge.

New or Little-known Plants.

Aster surculosus.

NEARLY related to *Aster spectabilis*, one of the most beautiful of the low large-flowered Asters of the coast-region of the northern Atlantic states and now sometimes found in the choicest collections of hardy plants, *Aster surculosus* replaces that species at the south, where it is found near the sea, growing in sandy soil from southern New Jersey to Georgia, and also on the Blue Ridge of North and South Carolina, where it abounds, and where it was first noticed a century ago by the French botanist Michaux.

Aster surculosus sends up low stems twelve to eighteen inches tall from long filiform root-stalks; they are covered with rigid, nearly entire leaves, which near the ground are oblong-lanceolate, and are linear above. The flower-heads are large and showy, with puberulous involucre and beautiful bright violet rays.

Our illustration (see page 521), which appears to be the first ever published of this handsome plant, was made by Mr. Faxon from a specimen grown in the Botanic Garden of Harvard College.

Foreign Correspondence.

London Letter.

ASTERS IN ENGLISH GARDENS.—The popularity of the genus *Aster* in England, and especially of that section of it known as Michaelmas Daisies, has had considerable development in recent years. Some difficulty has, however, been experienced by those interested in these plants owing to their names being almost hopelessly mixed, what was known by one name in one place being called by one or several different names elsewhere. The Royal Horticultural Society set itself the task three years ago of remedying this by gathering together for cultivation in their gardens at Chiswick all the shrubby Asters in cultivation. They then appointed experts to study these, and, if possible, reduce their names to order. This has been accomplished, or nearly so. Mr. Dewar, of Kew, was one of the appointed experts, and at a recent meeting of the Society he read a paper on the Asters, in which the views of himself and his co-workers are embodied.

In America you probably know a great deal more about Asters than is known here. At the same time, as a considerable number of improved varieties and supposed hybrids have originated in cultivation here, you will probably be interested in a résumé of Mr. Dewar's paper.

The Chiswick collection of Asters is now the largest and best-known in England. The supposed hybrids and garden-forms are planted side by side with the typical species, supplied from the Kew and Harvard collections. Professor Asa Gray was puzzled by the forms of American Asters grown in England, although, of course, he was thoroughly acquainted with the types. It is supposed that by a process of selection and cultivation extending over a long period in England the characters of some at least of the American wild plants have been more or less modified. The greater number of our Michaelmas Daisies are from species found wild in the eastern United States, few of those found in the west being in cultivation here.

Some of these Michaelmas Daisies are not properly Asters, Erigerons, Boltonias and Calimeris being included among them.

Mr. Dewar says that Asters cross or hybridize as freely

A. longifolius, are evidently most prevalent in the popular garden kinds, although there are something like twenty American species represented here. The named garden varieties are recommended as being much superior to the typical or wild species. A list of the best of the varieties will be published in the journal of the Society.

It is unnecessary to praise the Michaelmas Daisies as autumn-flowering plants. They form the most striking of the flower-pictures in the open air at Kew at this time of year. Massed in the mixed borders or planted alone in beds they are equally effective, and as they are among the easiest to cultivate of all plants, their claim to popularity is of the strongest. Mr. Dewar recommends them as bedding-plants, a purpose for which such kinds as *A. alpinus*, *A. acris*, *A. Amellus* and several others have been in use some years at Kew. Like all other plants, these Asters repay good cultivation. They like a deep, strong, loamy soil, and they should be dug up, divided and replanted every two or three years. Spring-struck cuttings of the young shoots form nice plants in a year. The tall kinds, such as *cordifolius*, *Diana*, *W. J. Grant*, *paniculatus*, *Lindleyanus* and *Arcturus* are suitable for planting to form single specimens on the lawn.

Dr. Masters remarked at the meeting when Mr. Dewar's paper was read that the Michaelmas Daisies, having now "caught on," are certain to improve rapidly in the hands of enthusiasts, as all other garden-plants have when thoroughly taken in hand. At present they are extremely beautiful in the garden, and equally so when arranged in vases. Possibly, however, in a hundred years' time the Michaelmas Daisy will be as far ahead of the present forms as the *Chrysanthemum* of to-day is of the plants from which they have been "evolved" by cultivators.

Besides the American Asters we have also some beautiful species and varieties of European nativity. Of these *A. acris* and its forms are first-rate plants for the border and flower-bed. *A. canus* and *A. Dahuricus* are equally good. Best of all is *A. Amellus*, from central and eastern Europe. There are numerous named forms of this species, the choicest of them being *Bessarabicus*, *amelloides*, *major* and *cassiarabicus*.

From the Himalayas we have the new and beautiful *A. diplostephioides*, which has tufted radical leaves and tall stems, a yard or so high, each bearing a large flower four inches across, colored rich lilac with a yellow disk. *A. Thomsoni* is one of the best of the dwarf autumn-flowering Asters, flowering from July to November. *A. Stracheyi*, also Himalayan, is a creeping species only a few inches in height, with small, but very numerous, blue-purple flowers.

Mr. Dewar also recommends several species from China and Japan, namely,

A. scaber, *A. Tataricus*, *A. trinervis* and *A. Maachii*.

ORCHIDS AT ST. ALBANS.—The month of October is, perhaps, the worst in the whole year for Orchid-flowers, but the best for an inspection of the plants themselves. The

Fig. 88.—*Aster surculosus*.—See page 520.

as the Columbines and Larkspurs do. He also states that "considerably over one-third of the Asters cultivated in our gardens are crosses or seedlings from *Aster lævis* and *A. Novi-Belgii*." These two species, with *A. paniculatus* and

gigantic Orchid business at St. Albans, built up by Mr. F. Sander, deserves a much larger space than you can spare to do it anything like justice; its enormous well-stocked houses, its labor-saving appliances, the comprehensiveness and health of the collections, the excellence of the cultivation, and the general interest of the whole establishment, I must not attempt to deal with at present. I had occasion to visit the St. Albans nurseries this week, and I propose to set down a few of the impressions made as I walked, during the whole of an afternoon, through the many houses in company with Mr. Sander and his clever lieutenant, Mr. Godseff.

Order, neatness, close attention to cultural detail; these are conspicuous features of this nursery. Large houses; but the plants arranged close to the roof-glass, plenty of hot-water pipes, light, a growing atmosphere, fed with plenty of moisture and the exhalations of lime, tan and leaf-mould, these are some of Mr. Sander's secrets. That they answer is evident in the health of the thousands of Cattleyas, the deep green, well-leaved *Ærides* and *Vandas*, *Cœlogyne Dayana* in thousands, with fine pseudo-bulbs and broad leathery leaves, all healthy, and growing with a vigor that suggested leeks. Of course, the grand *Dendrobium Phalænopsis* is there, flowering, too (it is never out of flower, Mr. Sander says), one spike bearing twenty-two large richly colored flowers, all open and fresh. *Cattleya labiata*, with hundreds of flowers and thousands showing; *C. Bowringiana* a broad cascade of flowers. *Dendrobiums* are not every gardener's successes, but at St. Albans they are perfect. There appears to be enough of *Odontoglossum crispum* to plant a ten-acre field, and the plants look as healthy as the healthiest Turnips. What an amount of real pleasure one gets out of looking at plants that are healthy and happy.

Sobralias are very numerous, some new in appearance, with distinctly marked leaves, beside *S. xantholeuca*, *S. leucoxantha*, *S. macrantha* and its variety *Alba*. *Lælia Perrini* filled one end of a house and was in full bloom; a beautiful Orchid, easily grown, for five years at any rate. *Cypripedium Schlimii*, growing in a moist cool corner, was healthier than I had ever seen it before, and flowering freely, too—I don't mean one plant, but perhaps two hundred fine specimens in eight-inch pots. *Cattleya Alexandra* fills, or nearly fills, the whole side of a broad house hundreds of feet long, and *C. Victoria Reginae* is equally abundant. *Barkerias*, *Catasetums*, *Miltonias*, *Calanthes* and *Thunias* are grown in great quantity, grown well and are flowering well, or promise to do so shortly. *Lælia anceps* is here in all its varieties, every variety in great numbers and apparently every plant showing flower. And thus it is in house after house, tropical Orchids of all kinds, intermediate and cool, everything good one might reasonably say, and enough of everything to supply everybody. The breeding-houses are stocked with seedlings in great numbers from *Cattleyas* to—well, I mustn't say what, but there are some promising miracles in those half-dozen houses which Mr. Maynard, who is a second Seden, has under his special charge. I must not omit to mention the many plants in flower of *Cypripedium Chamberlainianum* and *Renanthera matutina*, a most elegant orange-flowered tropical Orchid.

St. Albans is a great Orchid emporium. It is also great in other plants, or soon will be. Mr. Sander now devoting several houses to "new and rare" plants, other than Orchids. I was allowed to inspect the hidden treasures, and I saw there a considerable number of beautiful plants which are certain to find general favor when they are sent out.

We are often told that the nurseryman is only interested in plants as a means of making money, but what an enormous amount of valuable work he does for horticulture while filling his purse with guineas will be evident to any one who cares to study the history of garden-plants and gardening. The nurserymen introduce all the good things nowadays. Here, for example, is a quartette now abundantly represented and flowering beautifully, which we owe

to such business enterprise, *Vanda Sanderiana*, *Dendrobium Phalænopsis*, *Cattleya labiata*, *Cypripedium Chamberlainianum*.

Cultural Department.

Hardy Bulbs.

WHAT are generally considered hardy bulbs are, in reality, only so in name, and in the sense that they will live through the winter, even though frozen. In fact, but few bulbs produce their flowers as well after being frozen. Hyacinths are classed with the hardy bulbs, but in Holland, where they are grown to supply the markets of the world, they are protected with the greatest care. The beds there are thatched with reeds, which grow in abundance on the banks of the canals, as carefully and as warmly as the roof under which the family sleeps.

Nearly all the *Narcissus* are as carefully protected, and for the same reason. The *Crocus* belongs in the same list. Tulips are more hardy, but are greatly benefited by a slight covering of leaves, manure, or anything that will accomplish the purpose. It is the general opinion of those authorized to speak for the Lily that it is perfectly hardy. This opinion, supposed correct, not having been disputed, finds its way into seeds-men's catalogues, and is prominent in the "cultural instructions," where it does an immense amount of harm. It is founded on the fact that the species denominated hardy are natives of cold or temperate climates. While it is true that some of the species are found in the coldest parts of the habitable globe growing most luxuriantly, it is equally true that these same species are not hardy in our climate to a degree which renders it safe to plant them in our borders without protection. It is but proper to note that there is no climate more severe than ours on all bulbs that are considered hardy and left in the open border during winter. This is particularly applicable to the coast from Massachusetts to Virginia, where the thermometer often indicates forty degrees of frost while there is not a particle of snow on the ground to protect the bulbs. Here the frost penetrates the earth to a great depth one week, and is entirely out the next. These constant changes from freezing to thawing cause the earth to contract and expand to such a degree as to frequently tear the bulbs in pieces. We have had thousands destroyed in this manner.

But let us be more specific. Take the beautiful little *Lilium tenuifolium*, a native of Siberia, where it is largely grown as an article of food. In its native soil it is perfectly hardy, here it is not. Why? Simply because in its Siberian home the first indication of winter is a snow-storm that covers the ground so deeply that frost rarely, if ever, penetrates it at all, while here the earth is frozen to a depth entirely unknown there, notwithstanding their climate is much the colder of the two. The same is true of the *Lilium Martagon*, the bulbs of which are eaten by the Cossacks; in Russia it is perfectly hardy; with us, in the much milder climate, it will rarely survive more than a single season unless protected, and with that precaution it grows with more vigor here than in its native home.

In our eastern states, particularly in New Hampshire and Vermont, where the ground is nearly always covered with snow during the winter season, all kinds of Lilies grow to the greatest perfection. We have seen finer bulbs of *L. auratum*, *L. Brownii*, *L. Chalcedonicum*, *L. Martagon*, as well as other species, grown in these states without the least artificial protection than we have ever known produced elsewhere. There the bulbs named are always healthy and increase as rapidly as any of our native species, merely because their winters are always attended with sufficient snow to protect all vegetation against injury from freezing.

Nature is very considerate in this matter. Wherever the climate is the coldest there will be found the greatest protection given the vegetation. In our own woods there are many delicate little plants that are protected by their annual covering of leaves and snow, that we cannot grow in our borders without the most careful protection, and many of our native forest-trees struggle for an existence and finally succumb to winter's wind and cold when planted in the open.

The question may be asked, and it is a pertinent one, "Do not our native Lilies have the same elements to contend against as those not indigenous to our soil, and, having them, escape uninjured?" Certainly, yes; but nature always protects her own, and in collecting our native species we see how wisely and beautifully it is done. The *Lilium superbum* is rarely found excepting in moist woods or marshy grounds,

where the low-growing trees or shrubs form a network above and beneath the bulbs, affording ample protection against the action of the frost, should it penetrate the heavy mulching of leaves that nature has provided for their protection. *L. Canadense*, or common Meadow Lily, forms its bulbs very deep, usually beyond the reach of frost, as it has for a covering a very heavy turf, than which there can be no better protection. In our own nursery rows we find this Lily by no means hardy.

Whatever may be the cause of failure in the flowering of Lilies and Dutch bulbs of all denominations when planted in our borders, we are fully convinced, from our own observation and experiments, that when they are protected so that frost cannot reach them they will invariably succeed, and thrive in proportion as the other conditions of growth are more or less favorable; while those left unprotected, if in exposed situations, are quite as sure to fail.

The protection of a bed of bulbs is a simple and inexpensive operation. The best, because the most natural mulching, is a covering, say six inches in depth, of newly fallen leaves; these kept in their places by a few boughs or pieces of board, or by throwing a little soil over them. Coarse manure is a

the autumn-flowering group they are beautifully tessellated. *C. luteum*, however, is quite distinct from all other species. It is one of the spring-flowering kinds, a native of the Himalayas, with small bright yellow flowers. The plant would probably prove too tender for this locality, though it is said to be found at a considerable altitude in its native country. Like many of the other species, it is next to useless for ordinary decorative purposes, and its cultivation may wisely be confined to botanical institutions. The distinct color of the flowers may be of service to cross with one of the large-flowered kinds for a distinct hybrid; owing to the widely different character of the plants and their habitats the likelihood of success in such an experiment is decidedly problematical.

In general appearance the Colchicums bear a strong resemblance to the Crocuses, for which, indeed, they are often mistaken. The stamens, however, afford a ready means of identification between the two, there being six in the former, while the Crocus has but three. The underground stems are cormous (rhizomatous in *C. procurrans*), varying in size from that of a marble to that of a man's fist. The leaves also differ considerably in dimensions, being small and inconspicuous in

Fig. 89.—The Tan Bark Oak, *Quercus densiflora*.—See page 517.

splendid mulch, because it affords the protection required, and enriches the soil near the surface, where the feeding roots of the bulbs are to be found. Salt or marsh-hay is also an excellent protection, and not unsightly. In short, whatever material is most convenient and will accomplish the purpose is the one to be used.—*C. L. A., in the Florists' Exchange.*

The Colchicums.

THERE are about thirty species of *Colchicum*, mostly natives of southern Europe and Asia Minor. They may, for convenience, be divided into the vernal class, with flowers that appear in spring, together with the leaves, and the autumnal class, whose flowers are not developed until late in autumn, when the plants are destitute of foliage. The leaves of this last section are put forth in spring, but fade away in summer, not to appear again before the spring following.

The flowers are generally purple or white, running into many more or less distinct shades, and in some members of

some species, while in others they measure from twelve to eighteen inches long and three to six inches wide.

The autumn-flowering group contains the most generally useful species, and a few roots of the best of these should be given a place in every garden. Their flowers show up brilliantly when the glory of the summer garden is fast departing in September and October, and the plants are quite hardy, or require at most only a covering of withered leaves to preserve them from the severest frosts. The flowers without the leaves, it is true, present a rather forlorn appearance, but established masses of the plants afford so solid an array of bloom that foliage seems unnecessary, especially as there is an abundance of luxuriant foliage in most gardens at this season. The rich brown earth makes not a bad setting for their pleasing colors, and, as the autumn moves steadily onward, there is something of a fantastic charm about their mushroom-like appearance. They start like colored rockets from the ground, and shed a light which both illuminates and cheers their entire surroundings.

Colchicum autumnale, the Meadow Saffron of European

countries, takes a prominent place among the species. It was at one time a familiar autumn feature of the fields in the western and southern portions of England, where it was cultivated to some extent for the roots, said to yield a medicine of material efficacy in gout troubles, notwithstanding the fact that it is known to contain, in common with nearly all the other species, properties of a highly poisonous character. The plant retained a hold on those parts of England long after its systematic cultivation was discontinued, but at this time it is practically extinct there, a result of persistent collection by druggists and nurserymen.

The leaves of *Colchicum autumnale* are strap-shaped, deep green, and from nine to twelve inches long. The flowers are of a pale purple color, with narrow tube from four to six inches high, and limb from two to three inches wide, appearing about the middle of September, and lasting from a month to six weeks. There are many varieties of this species, the best of which, with the colors of their flowers, are *Album*, pure white; *Roseum*, reddish purple; *Atropurpureum*, deep purple; *Striatum*, purple and white; *Album Plenum*, double white; *Purpureum Plenum*, double purple. The double varieties are the more desirable, as the flowers last much longer. *C. Byzantinum* resembles *C. autumnale* somewhat closely, but it is a more profuse bloomer; the flowers are a pale rosy purple shade, and the leaves are much broader. This plant inhabits the Levant.

The best species of the genus is *Colchicum speciosum*, a native of the Caucasus. The leaves are of a bright green color, about a foot in length, and from three to four inches wide. The flowers are from nine to twelve inches high; limb cup-shaped, from three to four inches in diameter, and of a rich reddish purple color. *C. Sibthorpii*, a species only recently introduced from the Grecian mountains, is said to be a close rival of *C. speciosum* in the size of the flowers, which are of a deep lilac tint and obscurely tessellated.

Colchicum variegatum, common to the Levant and Asia Minor, is remarkable for the exquisite tessellation of its flowers, the colors being rich purple on a lilac ground; its variety *Parkinsoni*, which is sometimes accorded specific rank, has similar markings of a deeper purple shade on a pure white ground. The leaves have wavy margins, but in other respects these two plants and *C. autumnale* are much alike.

Colchicums do best in a light rich soil and an open position. The corms should be planted, according to size, from three to six inches beneath the surface of the soil, and, as the plants are most effective in large masses, they should be arranged in that way. This should be done as early in summer as practicable—that is, as soon as the roots can be had. The plants are easily increased by separating the corms, and they may also be propagated from seeds, though the latter is a slow process, as seedlings rarely reach the flowering stage before they are three or four years old. The seeds ripen freely, but they must not be sown until the early part of the summer succeeding the flowering season. They remain underneath the ground during the winter months, and are developed with the new growth in spring, rising beyond the surface to be ripened by the summer's sun. They should be sown in a cold frame when perfectly ripe, covering lightly with sandy soil.

Cambridge, Mass.

M. Barker.

Cape Oxalis.—III.

ANOTHER group of these plants consists of species whose flowers are large and showy, and produced single, and whose foliage consists of leaflets borne in twos or threes at the ends of the leaf-stalks; there is often, also, a foliaceous expansion on the sides of the stalks. These forms are so much alike that it is probable that they are not all valid species, yet as garden-plants they are enough unlike to merit distinctive names. They are all of easy culture, requiring no special soil or treatment. If potted at the beginning of September they will flower well in October and November. If they are kept dry until the middle of the latter month and are then planted in a cold frame and kept dark and cool through the winter they will appear above ground in April, and will generally blossom well, though some kinds will do better than others. They will survive with covering, as will all other *Oxalis*, without the protection of glass, but the wetness they then have to endure usually prevents the production of flowers.

Oxalis crispata has unusually large and broad leaflets growing in pairs, and the flowers are white, very faintly tinged with pink, much nearer a pure white than *Jacquin's* figure would lead us to suppose. *O. asinina* and *O. leporina* are named from the resemblance their long, narrow leaflets bear to the

ears of an ass and of a hare respectively; the resemblance, however, is not very close.

The flowers of the first are yellow, of a rather deep shade; those of *O. leporina* are white. *O. fabæfolia* is very ornamental from the great size and bright color of the leaflets, which grow in threes, and the large size and brightness of the yellow flowers. *O. lancæfolia* is a two-leafleted variety with yellow flowers not more than an inch in diameter. The number of leaflets given with each of these species is the usual number, which is not invariable by any means, for often the same plant will have leaves of both two and three leaflets. There are many other species, or reputed species, of this group, some of which I have, but they are so much like some I have described that I am not sure that they are correctly named, and therefore it will be better to say nothing more of them at present. Several species, with from five to seven leaflets and without leaf-like wings on the sides of the stalks, form another group of very distinct appearance. Their flowers are all yellow, of various sizes and shades, all striped outwardly with red, yet all sufficiently unlike to be worth growing. *O. lupinifolia* has from six to ten leaflets, that is six, eight or ten; the number is, I think, always even, and there is a dark blotch at the base of each; *O. flava* has five, seven or nine slender leaflets, so slender that several bulbs should be grown together to prevent a bare appearance. The seven or nine leaflets of *O. flabellifolia* are long and strap-shaped, quite unlike those of any other species. In *O. pectinata* the five or seven leaflets are somewhat fleshy and folded lengthwise, so that the opposite sides stand about ninety degrees apart. There are several species closely resembling this group from Mexico, Brazil and Chili, but no others, as far as I know, belonging to the Cape.

Fern Notes.

THE work in a Fern-house at this time of the year is largely of a routine character, but, nevertheless, it is far from being uninteresting, for there are constant attractions in watching the development of the fronds or surprises in the production and growth of seedlings. One very necessary precaution at this season is that of watering early in the day, so that the fronds may dry off again, for while a moist atmosphere is required at all times, yet a surplus of moisture on the foliage of the more delicate species will disfigure them. Another point of much importance is ventilation. Comparatively few Ferns relish a close atmosphere, with the possible exception of the Filmy Ferns, and it is, therefore, advisable to keep some of the ventilators open during the night as well as the day just as long as the weather will allow such practice. At the same time cold draughts must be guarded against.

But little potting is needed just now, except in the case of some small plants that will not carry through the winter in their present pots, for most of the larger plants will be nearly through with their active growth, especially those which are partially, or entirely, deciduous, and to this class a late potting is rather injurious than helpful.

A corner devoted to some seedlings of the more common sorts, such as those in general use among the florists, will prove very useful in helping to supply a mantel or table decoration when such may be needed. The plants for this purpose are most convenient when grown in three-inch pots, and for the same purpose a sufficient quantity of *Selaginellas* of such kinds as *S. Kraussiana*, with its variety *Aurea*, *S. Martensii* and *S. densa* may be readily grown under the benches in the Fern-house. Space can be thus economized, and what is frequently an unsightly portion of a greenhouse is covered and made presentable.

If space will permit, some of the smaller Tree-ferns should be planted out in the centre of the Fern-house, even if it be only a small stem or two of *Dicksonia antarctica*, as exemplars of this noblest class of Ferns. A pretty effect may also be secured by clothing the stem of a Tree-fern with a covering of one of the creeping species, such as *Oleandra nodosa* or some of the dwarf *Davallias*. Sections of an old Fern-trunk also make excellent material on which to grow the *Platycterium*, as they offer a congenial medium for the roots of the Stag-horn species, and have besides good lasting qualities.

Where exhibition Ferns are grown some staking is necessary, but it is well to remember that only enough stakes should be used to display the natural beauties of the plant, formal tying being an abomination when applied to a Fern. For this purpose steel wires are very neat, and are less noticeable when painted dark brown or black; in fact, I have used the ribs of an old umbrella more than once in staking a large *Adiantum*, and found them very satisfactory.

Thrips are to be found at any season of the year, and will spread much more rapidly on Ferns that are kept in too warm a temperature. The best remedy for them is tobacco-water, into which the foliage affected should be dipped. The decoloration should not be too strong if there are young fronds on the plant under treatment. Even weak tobacco-water is very distasteful to these insects, and, when used with reasonable care, there is little fear of injuring the foliage, except on such tender species as some of the *Cheilanthes* and *Gymnogrammes*.

To dispose of slugs the camphor method is best, as this gum can be spread among the plants in small pieces, or thrown into the centre of the crown of a plant without any likelihood of injury. It proves to be the most satisfactory remedy I have tested as yet. A special instance of the value of this treatment was brought to my notice last winter in a cut-flower establishment, where a Carnation-house had become badly infested with snails. The grower dosed a space of fifty feet in length with camphor, and, as a result, secured several thousand flowers from the plants in this area, while the remainder of the house was a total loss, owing to the work of the snails.

Holmesburg, Pa.

W. H. Taplin.

Magnolia Soulangeana.—It is, perhaps, noteworthy that this, one of our earliest and best Magnolias, is now ripening an abundance of fruit, and the large scarlet seeds are very conspicuous as they burst their covering. The plants also bear a fine crop of flower-buds, promising a rich floral treat next spring. This is undoubtedly the best early-flowering Magnolia we have, though its appearance lacks finish in the total absence of foliage at the time of flowering. The plant is of neat and compact habit, and the large, purple-tinted, white flowers are sweetly fragrant. The flowering season extends from February to May, inclusive, and it is early or late as the weather is mild or inclement. *M. Soulangeana* is of hybrid origin, having been raised in France by Monsieur Soulange-Bodin from a seed obtained by fertilizing the Chinese *M. conspicua* (the Yulan) with the pollen of *M. obovata*, a native of Japan. It is an improvement upon both parents, and perfectly hardy and reliable in our climate. A few successive warm days in early spring will sometimes induce the flowers to expand, and then they are easily injured on the return of frost, as was the case last season. A piece of light canvas or sheeting thrown over the trees in such an emergency will go a long way in protecting the flowers against serious injury.

Cestrum aurantiacum.—The bright orange-yellow blossoms of this species are very striking and attractive in the greenhouse at the present time. The plants were plunged in the open garden early in summer, where they flowered profusely during the first part of the season. They then made free growth, and were taken up and placed under cover a few weeks ago. *C. aurantiacum* is a native of Guatemala, and has been in cultivation since 1844, when it was introduced by Mr. Skinner, an English gentleman. It is of erect habit, and the alternate leaves are oval, pointed, of rich green color, margins wavy, and, with two-inch petiole, about eight inches long. The sessile flowers are tubular, with five reflexed segments at the apex, where they measure almost half an inch across. Their length slightly exceeds one inch, and they are produced in panicles. This plant is easily cultivated, and does well in any soil in which rich loam predominates. In winter it requires only sufficient heat to exclude frost, but established plants like all the light and sunshine they can get. Propagation may be effected by means of cuttings, which should be kept close and shaded until rooted.

Phygelius Capensis.—This is one of our most charming perennials, and one that will be popular when it is better known. It is treated in this country as an herbaceous plant, but is in reality a dwarf shrub of compact, bushy habit, and about three feet high. The reddish stems and branches are densely furnished with opposite, light green, ovate leaves, the edges of which are serrate. The leaves diminish in size from the base of the stem upward; the blade of the largest measures about four inches, and the petiole two inches in length. The drooping flowers are curved and tubular, an inch and a half long, mouth of five-pointed, spreading segments three-fourths of an inch in diameter, bright red on the outside, and orange-yellow within. They are borne very profusely at the extremity of the shoots in large, erect, tapering panicles, which often exceed twelve inches in length by nine inches through at the base, and the plant blooms continuously from early summer until cut down by severe frosts late in the autumn. *P. Capensis* is a native of Kaffirland, South Africa, where it grows by the sides of streams in the mountainous regions. It was introduced in 1855, by the

Messrs. James Veitch & Sons, of London, England. It is a good border-plant, thriving well in any good garden-soil, and if a thick covering of leaves is applied before the winter sets in the lower parts of the branches, with the roots, will remain uninjured by frost, sending up in spring shoots more vigorous than those of the preceding season. In the warmer sections of the country, with a little encouragement in the form of richer soil and frequent supplies of water in dry weather, it will doubtless grow freely and flower abundantly during the greater part of the year. Cuttings of the young wood root quickly in summer if they are inserted in pots containing sandy soil, placed in a frame under glass and kept close, moist and shaded. The young plants should be grown in a cold frame until the following spring, when, on starting into growth, they may safely be planted in an open border. Seeds are obtainable from flowering plants in large quantities, and they should be sown during the spring months. A little heat is necessary in raising seedlings, which should afterward be treated in the same manner as cuttings.

M. Barker.

Hardy Ever-blooming Roses.—My attention was recently called to a very fine specimen of the *Gloire de Dijon* Rose. It was growing alongside a house, and had reached the second-story window. Its beautiful rosy salmon-colored flowers were still abundant, as they had been all summer long. It ought to be more generally known that this climbing Tea Rose is one of the hardiest of its class. It needs no protection at all here. Speaking of climbing Roses, why is it that the *Crimson Boursault* is so seldom seen? It is true that it blooms but once a year, but many less handsome ones do no more. Its crimson flowers are most beautiful, and then, as with all *Boursaults*, it is almost free from thorns. Among Tea and Bengal Roses which live out with little or no protection here are the following kinds: Archduke Charles, rosy crimson; Malmaison, flesh and fawn; Sombrieul, creamy white; Homer, salmon and rose, beautiful in the bud; Hermosa, rosy pink, and Marie Ducher, salmon-rose. We plant these sorts in sheltered places near dwellings, or in borders where hedges protect them a little, and this is all the care they get in winter. Their tops are frozen down more or less, but as these Roses want a good pruning in spring this does not hurt them.

Germantown, Pa.

Correspondence.

Rambling Notes from the Ozarks.

To the Editor of GARDEN AND FOREST:

Sir,—One of the features of the Ozark Hills is the essentially local character of many of the trees and plants growing there. In the course of considerable wandering over half a dozen counties of south-west Missouri and north-west Arkansas, all in the Ozark Mountain region, I have found *Gentian puberula*, *Cypripedium spectabile* and *parviflorum* and an unidentified species of *Tillandsia* in widely detached localities, though often quite abundant in those places. I know of but two places in our county where the beautiful yellow Dog-tooth Violet is to be found, and of but one locality each where *Lilium Canadense* and the common Cat-tail are indigenous. Within a radius of one hundred and fifty miles of this place I have but once found Beech, Pecan, Shag-bark Hickory, Linden and Liquidamber, among trees; Black Alder, Wahoo (*Evonymus*), Leatherwood, *Celastrus scandens*, *Clematis Pitcheri*, *C. coccinea* and *C. crispa* and Wild Hop, among shrubs and vines; *Oenothera Missouriensis* and *O. speciosa*, *Viola pedata* alba, *Clitoria Mariana*, *Iris hexagona*, *Hepatica triloba* and *Cypripedium candidum*, among herbaceous plants; and *Nelumbo lutea*, *Nymphæa odorata* and *Nuphar advena*, among water-plants. Of course, there are many species of trees and plants that are common to all this region, but this but emphasizes the fact that other species, seemingly as robust and capable of dissemination, are to be found only within circumscribed limits, often but a few rods in extent. Probably the geographical position of this range explains the matter, extending as it does between the northern and southern portions of our great country. A close observer notices that many species common in the north are only occasionally to be found here, while there is quite a sprinkling of species generally found considerably farther south. The flora of the Ozarks has been very imperfectly collected. The lax cattle laws have caused many rare plants to be lost in the thicker settlements by the incessant browsing and trampling to which they have been subjected, but in the wilder mountain regions it is probable many valuable intermediate species can yet be found. It

is a thousand pities we Americans have to wait until our wild flowers are gone before we awake to their value.

July and August were hot, dry months in the south-west. A trip through the valleys at this time showed that the display of wild flowers was greater than the average display of cultivated flowers in village and country door-yards. There the early annuals had been burned up by the heat, and the autumn flowers were not yet in bloom. Not so the field and wood. The dry and rocky hillsides were dotted with white *Euphorbia corollatas*, rose-purple *Echinaceas* and the great purple-throated blooms of *Ipomœa pandurata*. The fence corners were fringed with scarlet *Silene Virginica* and magenta-colored *Callirrhœs*, while the meadows were seas of gold and white and pink, where the *Coreopsis*, *Sabbatias* and *Erigerons* nodded their countless blossoms in the summer breeze. Mother Nature's garden is always full, in spite of drought, because of her abundant supply of deep-rooted perennials and heat-loving, drought-enduring plants. There is a lesson in this for each of us, if we would but take it.

Another lesson we might learn with profit from a midsummer outing is the great value of fine-fruited plants. We used to think plants were only worth growing for flowers; then we learned to appreciate fine foliage as well; now we need to learn that few things are more attractive in midsummer, autumn and winter than plants and shrubs with beautiful fruit. How full the woods are of pretty things in that line! There are hundreds of dusky crimson spikes of *Rhus glabra* gleaming in the sun like jeweled passementerie, acres of the *Symphoricarpos* or Indian Currant, with their coral-like sprays of tiny red berries; there are bead-like fruits on the Black Alder, the Spicewood and *Cornus*, long strings of shining black berries on the Pokeweed and huge umbels of purple-black Elder-berries. To these we may add the homely fragrance and the dainty green of the wild Hop, the curious clusters of the Bladder-nut and the equally curious pale brown, warty clusters of Buckeyes. Nature has something for every season.

Lora S. La Mance.

The Sierra Nevada Forests.

To the Editor of GARDEN AND FOREST :

Sir,—An association styled "The Sierra Club" has recently been incorporated at San Francisco "to explore and render accessible the mountain regions of the Pacific coast; to publish authentic information concerning them; to enlist the support and co-operation of the people and the Government in preserving the forests and other natural features of the Sierra Nevada Mountains." Among the incorporators are many of the leading citizens of the country. The University of California and the Leland Stanford, Jr., University are represented upon the Board of Directors.

The beautiful forest-growth of California, its gigantic Redwoods, its magnificent Douglas Spruce, its glorious Pines (*P. Lambertiana* and *P. ponderosa*) are noted the world over. Hidden among these great trees, in shady recesses, are the sources of many living springs, which supply water to the plains below, thirsting for irrigation, and carry wealth, beauty and prosperity wherever they flow. While it is true that the snow-capped peaks of the Sierras furnish an ever-living water-supply to the rivers of California, still the forests, with their soft loam and deep-cut cañons, are in turn natural cache-basins, retaining the supply of moisture and gradually measuring it out to the surrounding country as regularly and as automatically as the flood-gates of a reservoir. If the forests are destroyed the water will rush down the rocky cañons and bare mountain-slopes without restraint, as is now the case in all the mountain torrents above the timber-line.

In the timber-regions no care is taken to prevent fires which every year destroy leagues of forest which a century cannot restore. Again: after the tree is felled by the lumbermen only one or two of the end or butt logs reach the mill, and the remainder are left to rot or to furnish material for a conflagration when the first careless mill-hand or sheep-herder passes by and builds his camp-fire.*

The State Board of Forestry of California recommends the withdrawal of the remaining unsold timber-lands and advocates laws to regulate the amount cut each year by the timbermen in order to prevent this wholesale destruction. The men who have formed the Sierra Club will aim to bring these matters to the attention of the people of California and create a public sentiment strong enough to be recognized by Congress,

* Mr. Hubert Vischer, C. E., in First Biennial Report Cal. State Board of Forestry (Appendix "A"), states that only seventy-three per cent. of logs cut are actually sawed.

so that prompt and efficient means may soon be used to preserve these natural parks.

These men are lovers of nature, but it is not sentiment nor a desire to interfere with a legitimate business of timber-cutting that influences them in this work. It is rather a conviction that the future agricultural development of the Pacific coast is at stake, and can only be secured by adopting some efficient means for preserving portions of the coniferous forests, which are the natural reservoirs of the Sierra Nevadas.

San Francisco, Cal.

Mark B. Kerr.

Fungus Troubles in the Orchard.

To the Editor of GARDEN AND FOREST :

Sir,—The Apple-leaf blight has been serious in Kansas this year, if we may judge from the following extracts from a letter written by a leading pomologist in that state. These statements are interesting in connection with the current discussions upon the Apple-scab :

"I am satisfied that the almost total failure of our apple-crop is due to the same cause as the failure in western New York two years ago—an extremely low temperature and excessive humidity prevailed before, during and after the blossoming-period, which augmented fungus growth. The leaf-growth was deformed, contracted and weakly, and the small apples, not larger than a small-sized marble, showed the presence of the fungus in a remarkable prevalence, as it caused about all the fruit to drop off, and the few which held on were so scabbed and distorted as to be hardly recognizable as apples, and soon after dropped also. Later on, the leaves showed the rust-colored spots, while the first growth curled up, and many dried up and died. The injury in old bearing orchards was quite noticeable in the later growth, which appeared stunted; at least, the development was not freely made, and below the standard of healthful trees.

"The present year is the first in the history of the country which has developed these conditions, and our people were unprepared to protect the orchards because not expecting such an attack. The same cause developed the Raspberry-rust to an alarming extent, and in some plantations the canes midway are as denuded of foliage as in winter-time. This, it seems to me, must weaken them and render them susceptible of injury by the winter's cold, and therefore materially lessen the next year's crop."

Cornell University.

L. H. Bailey.

A Good Hybrid Anthurium.

To the Editor of GARDEN AND FOREST :

Sir,—*Anthurium Greyanum* is one of the finest of the *Andreanum* section, and is a hybrid between that species and *A. ornatum*. The foliage is intermediate between the two, having the compact habit of *A. ornatum* and the bright foliage and free habit of *A. Andreanum*. The flower rises well above the foliage and is very attractive; the spadix, red-brown, two and a half inches long; spathe open, cordate-ovate, pure white, two inches across and three inches long. The name was given in compliment to William Grey, of Albany, New York, by whom it was raised.

Orange, N. J.

R. M. G.

Chrysanthemums at Short Hills, New Jersey.

To the Editor of GARDEN AND FOREST :

Sir,—Messrs. Pitcher & Manda seem to win a fair share of the prizes in the various Chrysanthemum shows each year. It is doubtful, however, if their greatest prize is not the reputation gained each season in their nursery. As is well known, they invite their friends several times each year to special exhibitions of plants and flowers. As the years go by these invitations seem to be accepted in increasing numbers, as visitors have found there a constantly enlarging and well-kept collection of fine plants. It is perfectly true that not even at the largest and best-furnished public horticultural show can a visitor see a tithe of the plants always on exhibition under these acres of glass. Then, again, there are people who enjoy flowers free from the blare of trumpets and the glamour of electric-lights. This week, as is their annual custom, the United States Nurseries opened the Chrysanthemum season with a private exhibition, at which were shown all the flowers which, later on, will be entered in the numerous exhibitions in all sections of the country. The Chrysanthemum-plants filled four of the largest houses of the hill-ranges. Each of these houses is some 250 feet long by sixteen feet wide, from which one familiar with the ample flowering habit of the plant

may gain an idea as to the mass of color. This same mass of color is usually the principal thing one finds to criticize at a Chrysanthemum show. Even when furnished with good foliage and helped by backgrounds and separating foliage-plants, the profusion of flowers and glare of color are apt to produce bewilderment and confusion rather than a well-defined enjoyment. In the upper house the plants were arranged for effect in a very tasteful way with sloping, irregular side terraces, and the main floor occupied by specimen plants, arranged cunningly, so that as far as possible as one followed the winding paths the beauty of each specimen could be enjoyed separately. And while the house was filled with flowers by the thousand, at no point of view was the scene oppressive. Two houses were filled with the new seedlings of the year under trial. There were said to be 30,000 of these, apparently a not excessive claim, as they were grown to single stems and planted in boxes at six inches apart. The lower range contained a selection of plants in readiness for the Madison Square Exhibition, where, no doubt, they will be heard from.

There was much to interest a Chrysanthemum-expert. In the first place it may be said that the plants were never grown so well here before. Good, strong, fine wood and well-developed foliage was the rule. It is always interesting to find new marvels, but one finds equal interest in observing how the marvels of former years are doing. It was pleasant to see so many of the former introductions of this nursery still showing their first form. To mention a few, Miss Annie Manda is a pure white incurved hairy kind, having the depth which the Mrs. Alpheus Hardy lacks. The Hicks Arnolds are again great balls of golden yellow. Mrs. E. D. Adams has improved each year, and is a massive white. A. G. Ramsey, when well grown, is a fine reflexed carmine, very telling. Mrs. Lewis is a very charming reflexed flower of a very pure clear yellow of medium depth. The great bronze Harry May was not seen in its former profusion. Mrs. Grace Hill, Mrs. W. A. Kimball and Mrs. Hood Wright seem to be a few of the other kinds which will probably stay.

One does not often have a chance to examine 30,000 new flowers, and the two houses occupied by these afforded a very striking illustration of the sportiveness of the Chrysanthemum. We are familiar with the fact that of so many thousands of human beings no two will be found exactly alike in appearance. We are not so familiar with the fact that we have a flower, of which two identical seedlings will hardly be found among many thousands. And this is the case even when many of the seedlings have the same parent. Of the seedlings here, a record had been made of the seed-bearing parent, and the flats of plants all bore pedigree-labels. Presuming this had been done with accuracy, the results were remarkable, each lot showing the widest possible diversities both in color and form, and often with no trace of likeness to the special variety from which it had sprung. A large number of hairy kinds in all colors and forms were seen, probably hybrids from Mrs. Alpheus Hardy, the female parent of very many of the new seedlings. Mr. Manda also claims to have secured from this variety many of his most distinct or fancy colored flowers, which he had in large numbers. Looking over the various flowers one could realize why each season so many new varieties are offered, for there seemed to be literally hundreds of first-rate flowers which any one would hesitate to discard. The new selections of the season were as yet unnamed, but some of the most promising numbers were No. 8, a fine spotted variety; No. 92, light yellow, reflexed; No. 42, incurved, white; No. 74, Stars and Stripes, white, striped red; No. 60, incurved, yellow; No. 78, salmon-pink; but it seems useless to detail under dry numbers the flowers which, no doubt, will soon be christened into the feminine gender.

The exhibition is primarily one of Chrysanthemums, because Chrysanthemums are just now in season, but no visitor to the nurseries will leave without at least walking through the great house where, under an acre and a quarter of glass, there are enough Palms to stock the Horticultural Building at Chicago if each one had all the room it needed. Two hundred and thirty species and varieties are represented here, and some of them are truly magnificent specimens. Here are Arecas, Kentias, Thrinaxes and many more with stems twenty feet high; besides Tree-ferns, a hundred of them, and many with trunks at least as long as the Palms, and several of them two feet in diameter. Under the broad and arching foliage of these Palms and Ferns and Cycads, of which there are some twenty-seven species and varieties, the visitor walks as if in the dusk of a tropical forest, while at the bases of the stems are masses of rare Ferns and other shade-loving tropical plants.

On either side, and opening into the Palm-house, are long ranges filled with stock plants in wonderful variety and in such

abundance as one rarely sees. One house is filled with *Kentia Belmoriana*, another with *K. Fosteriana*, a third with *Areca lutescens*, and a fourth with *Cocos Wedelliana*. Another still contains *Marantas*, *Crotons* and other stove foliage-plants, while the next gives space to nothing but *Anthuriums*, and the one beyond shows *Alocasias*, *Nepenthes* and the like. The house of *Dracænas* was conspicuous not only for the great number of well-grown plants it contained, but for the magnificent Stag-horn Ferns which ornamented its entrance, one variety in particular with a splendid shield being one of the most attractive plants in the whole collection. No one realizes the full decorative value of the *Auracaria* until a mass of it 200 feet long is seen; and beautiful as is a specimen plant of *Adiantum Farleyense*, a long house with both the centre and side benches completely covered with its soft foliage, gives one a new idea of its delicate and airy grace.

Of course, there are Orchids in bewildering profusion in the three ranges, each 500 feet in length. One is not surprised to learn that there are 2,800 seedling *Cypripediums* alone, and that the house which is filled with *Cypripediums* for flowering is 130 feet long. Just now the rare and beautiful little *C. Fairreanum* is in flower, and it seems to have a particularly tender place in Mr. Manda's regard, not only for its beauty, but because it seems gradually to be dwindling out of cultivation. He is fortunate in having among his prizes in bloom a hybrid between this species and *C. Spicerianum*. Of the other Orchids in flower which cannot be omitted are two distinct and charming varieties of *Vanda Sanderiana*, many fine examples of *Vanda cerulea* and the rare and beautiful hybrid *Cattleya Exoniensis*.

New York.

X.

Periodical Literature.

An interesting article in the October *Bulletin of the Torrey Botanical Club*, written by Mr. William T. Davis, describes the discovery on Staten Island of what he believes to be a new hybrid Oak. Near Watchogue, he says, grow numbers of the Black Scrub Oak (*Quercus ilicifolia*), associated, especially in the drier situations, with many Black Jack Oaks (*Q. nigra*). These species are easily distinguishable. *Q. ilicifolia* is not usually a tree, but a shrub. But, accompanying many normal specimens of both species, Mr. Davis noted many others, which, "when taken together, form a series leading from one species to the other, and apparently are hybrids resulting from the cross-fertilization of the two. Though these trees vary considerably, individually they resemble *Q. nigra* in being erect and rigid in growth, in their short, abruptly tapering branches, and in having the leaves rusty pubescent beneath. They resemble *Q. ilicifolia* in being small, in their smooth, light-colored bark, and in the retention of their dried catkins in abundance throughout the summer. . . . One of the trees that bears the greatest resemblance to *Q. nigra* is erect in growth and about eight feet high, and the leaves vary in shape from the *nigra* form to that of *ilicifolia*. They are more rusty pubescent beneath than those of *Q. nigra*, and the tree has a lighter appearance, owing principally to the color of its bark. Only two or three partly broken cups of last year's acorns remained on its branches, for it bore no fruit this year, but it retained its dried catkins in abundance.

"Another tree, that is about six feet tall and has the under surface of the leaves rusty pubescent, bore two abortive acorns this year, but retained its catkins. Still another tree, near by, is erect, about six feet tall, and has the leaves whiter beneath than the last. It bore no acorns, but, like the other trees, retained its catkins. None of the remaining trees so far discovered, the tallest of which is fourteen feet high, bore any fruit at all this year.

"At the other end of the island, at Rossville and Tottenville, *Q. nigra* grows abundantly, but *Q. ilicifolia* is absent, and a diligent search at these places resulted in the discovery of no such trees as those to be found at Watchogue."

In the list of hybrid Oaks contained in the last edition of Gray's *Manual*, two hybrids are described and named of which *Q. nigra* is a parent, and one of which is the offspring of *Q. ilicifolia*. But no hybrid between these two species is noted, and, therefore, as it is recognizable enough to deserve a name, Mr. Davis proposes to call it *Quercus Brittoni*, "after Dr. N. L. Britton, who was born on the island, and who, with Mr. Arthur Hollick, has done so much in making known its flora."

Notes.

We rarely hear the *Forsythias* spoken of on account of the beauty of their autumn coloring, yet these shrubs, although they begin to turn early to a rich chocolate-brown, hold their

leaves for a long time, and are still very beautiful, especially as the sun shines through them, when they show a very deep crimson tint.

At the Chicago Fair, Apache County, Arizona, will exhibit a collection of petrified woods from the famous forest-region along the Little Colorado River. Specimens of these singularly perfect petrifications, some of them enormously large, have been seen in this city, but will doubtless be new to very many visitors at Chicago.

The Chamber of Commerce of the twin cities of Winston and Salem, in North Carolina, at its last meeting passed a resolution recommending the Legislature of the state to acquire and preserve a portion of its forest-area, and urging upon the General Government the desirability and importance of a national park in the southern Alleghenies.

It is not usual to find Sweet Peas blooming in the open air on the 1st of November, but if the flowers are cut off every day the plants will always bloom until severe frosts. The unusually warm autumn has prolonged the season this year, and within a few days we have seen a beautiful bunch of these flowers picked from a row which had been blooming since July.

The proprietors of *Harper's Magazine*, in their announcements for the coming year, promise some illustrated studies of the old gardens of Italy, by Mr. Charles A. Platt, the well-known landscape-painter and etcher, besides other articles on "Our great pleasure-grounds in park and forest," while in another publication of the same firm Mrs. Candace Wheeler will write of "Color Effects in the Garden." This recognition of the fact that gardening is enough of a fine art to attract the pen and pencil of artists in other branches, and that it is a topic of sufficient popular interest to command an important place in leading periodicals devoted to general subjects, is certainly a gratifying one to all who love gardens.

Mr. E. H. Forbush, director of the field-work against the Gypsy Moth in Massachusetts, writes to Mr. Fernow, Chief of the Division of Forestry, to say that the insect-lime recommended by him (see GARDEN AND FOREST, vol. iv., p. 142) had been given a very thorough trial during the past two seasons. About four tons of the material have been used, and it was pronounced more useful than anything that the Commission has been able to secure or manufacture for the same purpose. The lime received from German manufacturers retained its freshness for a long time, and its only fault was that it hardened during cold storms and occasionally on cold nights, so that the insects could climb over it. If properly applied and watched it is very efficient, and seems more useful in woodlands than on street-trees, where the dust is continually flying.

Providence journals have recently stated that Neutakonkaut Hill will probably be bought by the city and reserved as a public pleasure-ground. The tract so called lies just outside the city limits on the Plainfield Pike. Part of it is level and covered thickly with woods, scattered among which are small farms, while another part is described as a "series of natural terraces, strewn with immense boulders, with here and there a giant Oak." From the highest point in this portion an extensive view of Providence may be had. From another elevation Fall River can be seen, and, in still a third direction, the wide and beautiful panorama of Narragansett Bay. A pond is also included within the limits of the indicated tract, and, as it thus seems particularly well adapted to its proposed purpose, its acquisition will doubtless be a matter of general rejoicing, especially among the large manufacturing population of the town, for, while Providence already possesses a number of small parks, it has as yet no large, varied and wooded tract suitable for popular refreshment on a generous scale.

Mr. F. V. Coville writes in a recent number of the *Bulletin of the Torrey Botanical Club* with regard to his rediscovery of a Rush (*Juncus Cooperi*), which was described as new by Dr. Engelmann in 1868 from a single specimen, without leaves or root-stock, collected seven years before by Dr. J. G. Cooper in San Bernardino County, California. It has since been known only through this single specimen, although Mr. Coville explains he has recently found another in the National Herbarium, falsely labeled *Juncus compressus*, and accredited to the Colorado Desert in California. In January, 1891, he tells that an expedition sent out by the United States Department of Agriculture, entered Death Valley and encamped at Bennett Wells. Near this camp, and in several other places in this same region, he found *J. Cooperi* in fruit, standing on the borders of a salt-marsh amid vegetation peculiar to this alkaline region, "in tufts sometimes composed of only a few stems, or occasionally attaining the extraordinary diameter of two metres."

A full description of the plant, drawn up from these living specimens, accompanies Mr. Coville's account of its rediscovery.

About a year ago GARDEN AND FOREST told the story of the creation of Highland Park (see vol. iv., p. 553), which was secured for the old village of Jamaica, Long Island, by an organization of public-spirited women. One of the interesting features of the ceremonies of Columbus Day in Jamaica was planting memorial trees in this park under the auspices of the Linnean Club. Trees were planted in honor of Columbus and Isabella, of Mr. Brinkerhoff, who gave half the cost of the land in the park, besides one in honor of each of the original incorporators of the Park Association. During the exercises it was announced that Mr. Henry A. Van Allen had given an acre of ground which bordered on the pond, of which the association owns only a part. This donation is the first step toward obtaining control of the entire shore, and a "Van Allen tree" was very properly added to the collection. The trees were planted under the direction of Mr. Henry Hicks, of Westbury, Long Island, a graduate of the School of Horticulture in Cornell University, and since he took a special course in landscape-gardening there is reason to believe that the trees are not only carefully planted but properly selected and placed.

A French writer having stated that, so far as he knew, the Purple Beech had never been planted as an avenue-tree, the *Monthly Bulletin of the Horticultural Society of Mons* recently informed him that an avenue of Purple Beeches, still young but flourishing, exists in that part of the forest of Soignies, which lies near the Boisfort race-course. We may say, in our turn, that a fine avenue of large and well-developed Purple Beeches is a conspicuous feature of an old country-place near Boston, the trees varying in color from a true purple to a rich dusky bronze. Few persons will regret that avenues of this kind are infrequent. Green is nature's color, in the sense that it is the only color which she uses in large masses of foliage. The original Purple Beech was a "sport" from the common species. It was wise to propagate it for garden use, as a single bronze-colored or purple tree as beautiful in form as the Beech, used as an accent to relieve great expanses of green, may be advantageous in a diversified landscape-gardening scheme. But the presence of even two or three such trees can seriously disturb the repose and unity of a lawn or plantation; and an avenue of them, while appealing, by its conspicuousness and rarity to the wonder of some observers, can never be as appropriate or beautiful as an avenue of green trees of this or another species.

The monument to the memory of Audubon, which was projected for this city some time ago by the American Association of Science, is nearly completed and will be unveiled by the great naturalist's granddaughter before the first of December. It will stand in Trinity Cemetery, near the Audubon family vault, and will eventually face Audubon Avenue, as this street is to be cut through to 155th Street. The Audubon family once owned all the tract of land lying between the Hudson River, Tenth Avenue, 155th and 158th Streets, and a portion of it is now called Audubon Park, although it is not a public property, consisting of a group of villas, surrounded by more or less extensive grounds. Some contributions for the monument came from other states, but the major part of the money was raised in New York, largely by the exertions of Dr. Egleston, of the Columbia College School of Mines. It is composed, we are told, of a large square block of bluestone, bearing a relief-portrait of Audubon and various appropriate emblems. This is surmounted by a Celtic cross, nineteen feet high, carved with characteristic Celtic designs, in which basket-patterns, flowers, birds and animals are interwoven, and with Biblical inscriptions on the panels at its base. The scheme is evidently a good one, but one may doubt whether the execution of it will be as good, for the work has been done in a stone-yard, without the assistance of any artist whose name is familiar to the public.

Catalogues Received.

DAMMANN & Co., San Giovanni a Teduccio, near Naples, Italy; Flower and Vegetable Seeds, Seeds of Shrubs, Conifers, Palm and Fruit Trees, Bulbs.—E. HIPPARD, Youngstown, Ohio; Standard Ventilating Machinery, Standard Hose Mender.—WM. S. LITTLE, Rochester, N. Y.; Ornamental and Fruit Trees, Fruit-bearing and other Shrubs, Vines, Roses, etc.—HUGH LOW & Co., Clapton Nursery, London, N. E., England; Wholesale Trade-list of Orchids, Palms, Ferns, Shrubs, Trees, Roses and other Flowering Plants.—PITCHER & MANDA, United States Nurseries, Short Hills, N. J.; Select Plants for Artistic Decorations, Hardy Perennial and Herbaceous Plants for Fall Planting.

The Beautiful in the Surroundings of Life.

MR. HAMERTON has well defined the word "landscape" as meaning "the visible material world, or all that can be seen on the surface of the earth by a man who is himself upon that surface." Wild landscape—the scenery of the natural world—possesses infinite interest and charm for those of us who live caged in towns and cramped in houses, and we greatly enjoy both traveling in search of it and reading the praise of it. No age of the world has ever brought forth so many delightful books about the woods, the mountains and the sea-shore. The beauty of natural scenery stirs us as does the finest music. As Mr. Symonds has noted, "there is a profound sympathy between music and fine scenery; they both affect us in the same way, waking strong but undefined emotions which express themselves in 'idle tears' or evoke thoughts which lie, as Wordsworth said, 'too deep for tears' beyond the reach of any words." It seems as if our extreme delight in the beauty of wild landscape, tending, as it seemingly does, "to destroy habits of clear thinking and to sentimentalize the mind," had caused us to overlook for the time the supreme importance of that part of landscape which is necessarily not wild—the landscape of our daily lives—the humanized scenery of the earth. This prevalent carelessness concerning the landscapes of every-day life is something remarkable. Here are our rich men paying enormous sums for painted landscapes to be hung in their houses while they permit the real landscape about them to become ugly in the extreme. Here are poorer people spending liberally for journeys in search of the picturesque while what might be the picturesqueness of their own neighborhood is unperceived or destroyed.

But there are signs that a better day is coming. Some parts of our great America are even now beginning to stir with eager desire for beauty. It is true, the desire is unformed, and our work is too often based upon mistaken conceptions of that beauty which is our hope, and yet we

must be thankful when the desire appears among us, for it is something which distinctly ennoble the life of every man and nation in whose heart it is born. Possessed by it, we are compelled to strive and strive again to find "the secret of the beautiful," the foundation upon which beauty is built, the nature of that growth of which beauty is the flower. We shall make our mistakes like other men. We shall attempt to attain our heart's desire by forbidden and impossible ways. We shall probably fell noble forest-trees to make room for brilliant exotics. Perhaps we shall curve our roads because we think we like curves, or build our houses according to some pattern we admired in a foreign land. But, even so, there is hope for us. We shall learn in the end. And, meanwhile, so rash and willful and so generally unsuccessful are we in all this field of work that it may be worth while to look back for a moment over the long story of the evolution of landscape in the hope that we may find therein that key to the secret of the really beautiful which we seek.

Not to name others, Mr. Ruskin, in his early essay on the Poetry of Architecture, has been before us here. He finds man in primitive ages living precariously upon wild nature, and causing little or no change in the appearance of the wilderness around him. When, at last, he is forced to increase his food-supply, he takes some wild thing like maize and plants it in the glades of the forest, and stores the crop in granaries set up on stakes. When he desires to shelter himself, he contrives frail tents like the Bedouins or the Red Indians, or he walls the mouths of cañon caves, or he builds earthen pueblos hardly to be distinguished from the arid ground on which they stand. As he comes to cultivate broad stretches of the earth, he works marked changes in scenery. He fells the woods and marks off fields and draws lines of roads across the country. He plants avenues and orchards, he makes gardens and vineyards, he builds farmsteads of as many types as there are differing climates and differing social circumstances, he builds villages and cities, he rears palaces and temples, doing all to meet his needs and to express his life; and so long as he is sincere and straightforward in his work, mother Nature stands ready to adopt it as her own, and to make of it landscape rich in meaning and pathos such as no primitive wilderness can show.

Look for a moment upon a typical valley of the interior of our own New England. We are standing upon the eastern wall of upland. The village, with a mill or two and a church or two, lies below us at the mouth of a gap in the northern hills. Southward the valley broadens to contain a fresh green intervale. Opposite us the western wall of the valley is an irregular steep slope of rising woods, with numerous upland farms scattered along the more level heights above. The central intervale, the flanking woods, the village gathered at the valley's head—the whole scene before us possesses unity and beauty to a degree which interests us at once. And how was this delightful general effect produced? Simply by intelligent obedience to the requirements of human life in this valley. The village grew what it is for the sake of nearness to the great water-power which rushes from the gap in the hills. The intervale was cleared and smoothed for raising perfect hay. The steep side hills have been maintained in woods because they are too steep for agriculture, and because, if they were cleared of trees, their sands and gravels would wash down upon the fertile land of the intervale. Similarly upon the upland farms, the greenery along even the tiniest brooks has been preserved in order to obviate that wasteful washing away of soil which results from carrying plowing to the edges of the water-courses. Throughout the landscape before us it is most interesting to note how beauty has resulted from the exercise of common sense and intelligence. The every-day forces of convenience, use and true economy have here conspired with Nature to produce beauty, and this beauty is of a very different and much more satisfying kind than that which tries to found itself on mere caprice or fashion.

If, now, we search the world over, do we not find the same truth everywhere? Let us call to mind some of the loveliest of earthly scenes. The red farmstead among the Firs of Sweden, the Ilex-trees and the white villas of the steep bank of Como, the English deer-park and its stately mansion, the towered village of the Italian hills, the broad green and the great Elms of our own Hadley or Deerfield. The beauty of these memorable humanized landscapes is nothing extraneous; it is not something added to the landscape after the main lines have been laid down; it springs directly from the fact that these fields, trees, ways and buildings have been arranged first with reference to the needs, uses and enjoyments of real life in their respective lands and climates, and it is their perfect conformity to these principles which constitutes the essence of the beauty we admire. Not by display of knowledge of the styles of architecture and gardening; not by gathering in one place all the trees of the earth; not by imitating the beautiful features of the scenery of foreign lands and climates; not by copying wild nature in places which are not wild; not even by attempting to obey the laws of landscape-painting, will beauty ever be won to dwell among us in the surroundings of modern life. "All that would be fair must be fit." There is no other way to win the beauty we desire.

This truth being accepted, what shall we of this too self-conscious age say to our gardener and our builder when we set out to make "a place of our own"? To the first it must be: Lay out no road or path which is not the most convenient possible in the circumstances. Lay out nothing for mere flourish, but all for use or rational enjoyment. Fell and plant and choose the kinds of plants for good reasons only. In all you do, have constant reference to the general scheme of the whole place.

To the builder we say: Plan for convenience first and always. Take advantage of every peculiarity of the purpose, the site and the exposure of the building. Let the exterior of the building faithfully represent the interior, and shape it not as a thing apart, but as the central object in a larger design. In placing doors which involve paths; in arranging drying-yards, kitchen-courts, piazzas and terraces; in all you do, have constant reference to the general scheme of the whole place.

And who shall conceive and insist upon this general landscape scheme in the perfecting of which the artist gardener and the artist builder are to play their respective parts? In these days it is seldom that the need of such a broadly inclusive scheme is realized even by the artists who have part in the work, much less by the managing owner; and yet the time is coming when the landscape-architect, whose province is just this arranging of the building and its surroundings to form one landscape, will be welcomed alike by owner, builder and gardener as the man who will cause the work of each to count for beauty much more effectively than it otherwise can. When this day comes, and either the owner, the gardener, the builder or the professional specialist is looked to as the deviser of a general landscape design based on purpose and fitness, and not upon caprice; then, again, there will be hope of finding the really beautiful in the surroundings of daily life.

OUR attention is called by the *Boston Commonwealth* to the fact that Samuel Sewall celebrated Columbus Day in 1692 by planting five Chestnuts. If these Chestnut seedlings had been carefully nurtured as memorials of the second centennial of the discovery of America, the great trees as they were about entering upon the third century of their existence would now be objects of the deepest veneration. We are glad to learn that in many places, as in the new park at Jamaica, Long Island, memorial trees have been planted this year in honor of the fourth centennial of the great discovery. Four hundred years hence, an Oak carefully planted now and duly nourished and protected from year to year, would have a value beyond that of merely

directing the attention of future Americans to the daring navigator who found the western shore of the Atlantic. We are beginning to be old enough to have a past, although our most venerable date is modern compared with those of European history. We scarcely realize how the doings of the day will look to the generations in the thirtieth century, who will turn to our records as we revert to those of the Ancient Britons and study the marches of Cæsar. It is a novel thing for us to pose for posterity, but the time has come when it will not be considered altogether frivolous on our part to have some care for statuesque effect a thousand years hence. If we now take heed to establish customs honorable and worthy of veneration we shall then have groves which will compel the same reverence as that with which we regard the park of the Druids and the Olives of Baïæ.

Any custom which encourages the intelligent planting and care of trees is worth establishing and cherishing. If forestry is ever to assume its proper place in public instruction, beginning must be made with the children, and we must impress upon them from earliest youth the value of trees in the economy of nature. They must be taught the importance of preserving our woods and be made to feel that it is the solemn duty of the generations to come to cultivate and guard these bulwarks of our national prosperity. No course of physics should be considered complete in our common schools or our higher institutions of learning which does not include the influence of trees upon agriculture and civilization. But the intellectual appreciation of the economical value of trees is worth a great deal more when this knowledge is vitalized by an admiration of their beauty and a genuine affection for them. Our forests will only be safe after we have become a nation of tree-lovers, and the foundation of this regard can be laid in no way so well as by enlisting the interest of children in individual trees. Memorial trees, grouped on school-grounds or supporting a town-hall, if they have been planted with some ceremony by the children of the place and entrusted to their care under the supervision of their elders, would become in time objects of deep personal regard. This affection for the tree by its planters and protectors will grow stronger as all grow together. No one who has developed a love like this for any one tree can witness the useless destruction of another without a feeling of pain and indignation; and we can never look for an assured protection of our woodlands until the mass of the people of the country are not only instructed as to the important function which trees perform in the economy of a civilized nation, but have been brought up from childhood with a growing appreciation of their beauty and a constantly deepening affection for them as if they were personal friends.

The Columbian anniversary, then, will be a genuine advantage to the nation, if it helps to establish the custom of planting and caring for memorial trees.

Mount Desert—A Foreigner's Impression.

THERE is much to sadden the heart of the lover of garden and forest on Mount Desert island. The sight of the woods is lamentable. One day we drove past mile after mile of half-grown, tangled, choked and airless woods, filled with falling trees and rotting rubbish, and rendered still more uncanny by the numbers of dead trees standing like dreary ghosts, that could not even move about, fettered in the stony soil. And when, after a few miles of this, I could not help saying that "I had never seen worse-kept woods," I fear I exposed myself to ridicule.

It was carefully explained that America had no need of forestry, and one would judge so indeed by the lavishness with which splendid logs were piled up in the generous fire-places. Yet wood is worth something in Boston, and the splendid logs themselves give little pleasure to one who sees them burning after he has observed that trees of the calibre they represent are none too many for beauty, that is the landscape beauty which ought to be such an important element in a summer playground.

Good forestry takes landscape beauty into account, and although it might seem ludicrous to propose, in a poorly populated district like Mount Desert, to thin out the rubbish which is such an offence to the eye of one accustomed to Swedish woods, yet at least the finest specimens might be left and a few more of the indifferent trees taken instead.

But the great end and aim of practical forestry is utility, and in this respect there is much to astonish the foreigner in the state of things on the large, wooded island of Mount Desert. We do not sweep our forests with a broom, as some Americans believe, but we treat them as we should any other valuable crop, trying to favor its growth and not leaving it to fight unaided against its enemies. It will not be long before America, at the pace she is going, will have to give up the fiction of youth, which is now offered as the excuse for all wastefulness, and begin to profit by the experience of her elders, who are bitterly ruing the day when they squandered their patrimony of seemingly exhaustless woods. The forest on Mount Desert seemed to me to be just in that stage of secondary growth when interference becomes imperative, both to preserve the fine trees and give them the opportunities they deserve and to make a good crop in the thickest places out of a poor one. Natural selection would ultimately do the work, but who has time nowadays to wait for the slow process of natural selection?

In the landscape-gardening here, good tendencies and successful results are seen side by side with what must be called perversity of taste. (I am not here speaking of Bar Harbor, which I did not happen to see.) Why spend untold gold in making and keeping a lawn on this rocky soil when the unobtrusive shingle houses, with their surroundings of bare rock and native Spruce, have a fascination which no one can resist?

Of course, there is something to be said for the lawns, too, as symbols of contrast, as a little glimpse of city luxury for those who care for that in the midst of this unkempt nature. Only to make the contrast telling the lawns ought to be of the most velvety and sparkling turf—ought to be framed in an immediate setting of wild woods, or be set apart by enclosures from the vulgarity of the semi-villages. Coarse villages are here even more than elsewhere a very poor substitute for the natural "wild garden" they have replaced, and the sight of expensive lawns, on which the hose is constantly spurting, surrounded by cheap houses and shops with plate-glass windows, only suggests a needless and tasteless outlay of money; and this is vulgarity.

However, I did see a few very successful combinations of lawn and wild scenery, and one in particular. The house is situated on a point at some distance from the main road, and communicating with it by a long straight drive, with the low brushwood on either side left quite wild except for a narrow strip of turf along the drive. Spreading lawns, studded with the beautiful natural evergreens of the region, surround the house on every side. On the inland side these trees are made to serve as a dark background for a set of bright flower-beds fronting the main entrance; on the piazza and sea-view side, the lawn is kept clear, save for groups of graceful Larches, Spruces and Pines that contrast effectively with the smooth gleaming turf and merge insensibly into the wild strips of wood left in places here and there.

But the most charming creation had no lawn at all. It made all the more impression on me for my coming on it one morning unawares after a week of perplexed wonder at the state of the woods and the lack of taste and the absence of any unity whatsoever in the arrangement, or non-arrangement, of the summer settlements. I had been seeing not only unkempt forests and human habitations grouped together in the ugliest possible way; I had also seen some splendidly wooded rocky promontories, plunging their dark masses into the clearest of tidal seas, and left unspoiled by the happy mortals who had there set up their summer abode; I had seen superb, far-spreading views, and some very beautiful, interesting and altogether satisfactory mountain-sides, which might have been in Sweden except that the place of the Red Oak, our pride and joy, was taken by White Pines and Pitch Pines, and that Moose-wood, White Maple and Yellow Birch mingled freely with the White Birches on the stony slopes. Yet all these beauties of nature only made me feel more keenly the mistakes in taste and want of care displayed, and it was in this frame of mind that I came upon the little "creation" aforementioned. It is a mere little log-hut or lodge standing by itself in the woods on the slope of the mountain of Asticon. It is dark brown in color, has a picturesque gable with some carving, a high foundation, and a raised, very effective, rough piazza along two sides of the house. It was closed, and with a very formidable padlock,

too, so I could prowl about freely. The site was exquisitely chosen, giving a view from the piazza that seemed the very essence of Asticon; the peaceful harbor cradled by wooded hills with the broad expanse of sea and islands beyond. The situation was full of the poetry of *Waldeseinsamkeit*, for which the German has so many condensed expressions and the English so few, and the whole place lying there silent, basked in the sun, among the mossy ledges and tall Arbor-vitæ, somehow like the wood-hut of The Three Bears. Very little had seemingly been done to it, but a great deal of thought had been put into it, and one little touch of visible art went very far toward deepening the charm. On the slope, in front of the piazza-steps, there was a thick grove of tall Arbor-vitæ. Through these a passage, or tunnel, had been cut, accentuated by a low stone wall, leading part of the way up toward the piazza, the whole giving a faint suggestion of foreign lands and conscious art, that only served to heighten the imaginative charm of the place.

Truly, the art of landscape-gardening does not always consist in spending a lot of money in transforming nature.

New York.

Cecilia Waern.

Botanical Notes from Central Texas.

THESE notes are written from the city of Lampasas, which lies in the north-west angle made by the intersection of the thirty-first parallel with ninety-eighth meridian. The city is situated in the valley of Sulphur Creek, and is the capital of a county of the same name. The creek takes its name from the numerous sulphur springs which issue from its bank or from near them, and keep up its perennial supply of water. Within the city limits there are two springs whose waters are so strongly impregnated with sulphur as to leave incrustations of that mineral upon the rocks and plants over which they flow. Each of the springs is the source of a little brook.

While Lampasas may be considered to be the base of these observations, still many of them were made in Burnet County and around the city of Llano. We are now in old Texas. The western part of Burnet County and portions of Llano County are very old—so old that they are considered to be synchronous with the Iron Mountains of Missouri, the Black Hills of Dacotah and the Laurentian Hills of Canada, and with them stood out as solitary far-separated peaks above the primeval sea long before the Rocky Mountains were upheaved. The ninety-eighth meridian, more nearly than any other, is the dividing line between the vegetation of eastern Texas and the Mexican flora of its western border. It is largely the common ground where adventurous species of both sections meet.

The characteristic tree of this region, and the most valuable one, is the well-known Pecan (*Hicoria Pecan*). When this species lays itself out for a supreme effort it attains a much larger size than its congeners, becoming a hundred feet tall and four feet in diameter. An important and growing trade in pecan-nuts already adds millions of dollars to the wealth of Texas farmers. A large tree under favorable conditions may produce ten bushels of nuts in a year. Live Oak is, next to Post Oak, the commonest Oak in central Texas. It also attains a larger size than any other Oak attains here. A peculiarity of this species is the formation of dense groves, "mottes," sometimes covering only a few rods, sometimes several acres of the other naked prairie. I asked a native Texan for the origin of these groves that form so distinctive a feature of the landscape of central Texas. He replied, "They come from the roots of some old tree that is now dead and rotted away." They may have come from the thousands of acorns which some old now-gone tree had planted. *Quercus Durandii*, *Q. nigra*, *Q. macrocarpa* and *Q. coccinea* are also here. Hackberry (*Celtis*) in several forms is common. Whether the numerous forms under which it appears constitute a single species or more than one is a question for systematists. If there be more than one, there are probably four. Botanists have nothing to do with making species. They have only to learn, if possible, how many species Nature has made—whether one or a dozen of a genus they should not care. The question then comes up, What is a species? There the trouble begins. It may be true that sometimes with too much freedom we dignify slight variations of form in plants as varieties, and couple too many specific names with the hybrid symbol without having made one experiment to learn if the united species would hybridize, or, if they will hybridize, that the hybrid is like the form that we have found. It may also be true that in our desire to do original work we have not given sufficient prominence to the range of individual variation in plants—a variation that may fill the entire gap between species without ever crossing the line that separates them.

White Elm (*Ulmus Americana*), *U. crassifolia* and *U. alata* are abundant. What I suspect to be *U. crassifolia*, as I have no description by me, is at this writing in full-ripe fruit. It blossoms late in summer, and, like other Elms, takes a few weeks only to ripen its fruit. There is also an Elm here in fruit with strongly winged branchlets. Near Fort Smith, Arkansas, *U. alata* was loaded with nearly ripe fruit as early as the 1st of April.

The Button-bush (*Cephalanthus*) is common along streams, and the species is sometimes arborescent. I have seen individuals nine inches in diameter. Wild Black Cherry (*Prunus serotina*) grows near Burnet. Wild Plum (*P. Americana*) is abundant. The handsome little shrub *Dalea frutescens* is common on the summit of Post Mountain, and there the western Honeysuckle (*Lonicera albiflora*) begins to appear.

Vernonia Lindheimeri is everywhere on the limestone hills of central Texas. On richer soils lower down the hillsides, a handsome *Erythraea* during the month of August covers the ground with its bright pink flowers.

Mesquit (*Prosopis juliflora*) is nearly everywhere, and Texas would hardly be Texas without it. With wood serving for fuel, and seeds for animals, and for human beings when hunger pinches, it is invaluable for beast and man. Usually a small tree, it often becomes sixty or seventy feet tall, and two feet or more in diameter.

In rocky places, conspicuous by its long lithe branches covered with small, white and sweetly scented flowers, grows *Lippia ligustrina*. It is often seen in cultivation, to which its beauty and odor entitle it. There is no Texas shrub whose flowering sprays are better adapted for delicate, odorless bouquets. *Eysenhardtia amorphoides*, a small shrub of the Pea family, is often found in company with *Lippia*. Although burdened with such a name, it bears handsome white flowers that are pleasantly odorous. Soapberry (*Sapindus acuminatus*) is often seen in this region, where it becomes a handsome tree. It is more commonly known in the south as "Wild China," from the resemblance of its unripe fruit to that of the China tree, *Melia Azedarach*. *Sapindus* seems to have overlooked the fact that high botanical authority asserts that the common petiole of its compound leaf is never winged; and it persists in making its common petiole strongly margined or winged between the leaflets, at least in young trees, as specimens collected in Kansas and in Texas show. The Mexican Buckeye (*Ungnadia speciosa*) is very abundant on rocky banks and bluffs throughout our range. It grows eastward as far as Harris County, and extends far westward. Commonly a small shrub, it sometimes becomes a tree of respectable size. The largest individuals that I have seen were on the banks of La Vaca River, near Hallettsville. They were over a foot in diameter and thirty feet tall. The discovery of this species, as botanists know, marks an epoch in systematic botany. The fact of its being really a pinnately leaved Buckeye gave us *Sapindaceæ* in its present form. The rose-colored flowers are large and handsome. Each cell of its triangular fruit contains a shining dark brown, small roundish seed, closely resembling a small Buckeye-seed.

The forms of *Rhus copallina*, known as variety *lanceolata* and variety *leucantha*, are very common west of the ninety-seventh meridian. *Toxicodendron* is nearly everywhere. This species, as now defined, is in a sadder condition than even *Celtis*. It is often seen climbing seventy-five to one hundred feet high, throwing out strong horizontal branches sometimes ten feet long. It is sometimes a weak, straggling, nearly erect shrub; a low form, not more than a foot or two tall, covers hundreds of acres of the prairies of western Kansas. The western form of *R. Canadensis* is also common in rocky places. *R. virens*, with handsome evergreen leaves, is found along Colorado River and on the mountains near Llano. Its rather large white flowers appear in September, and are succeeded by bright red fruit.

At Marble Falls I met for the first time in Texas *Solanum heterodoxum*. It closely simulates *S. rostratum*, having the same watermelon-like leaves; but they are more viscid and the plant is taller and slimmer, and has bright blue flowers. *S. elæagnifolium*, *S. Torreyi*, *S. nigrum* and *S. triquetrum* are common. The last-named species is slender-stemmed and clambers over rocks and bushes. Its specific name alludes to its somewhat triangular stems.

Granite Mountain gave me my first view of the handsome fern, *Pellæa ternata*. *P. flexuosa* is very abundant along the rocky bluffs of Colorado River, and both species, with other ferns, grow on Sand Stone Mountain, near Llano. Around the mountain and everywhere in sandy places the eastern *Zornia tetraphylla* grows like a weed. It is here slighter and more erect than it is in the east. *Philibertia undulata* is

rarely found near Llano, and also *Desmodium Wrightii*, remarkable for being unifoliate.

Galactia heterophylla grows abundantly in the streets of Llano. This species was first discovered by Lindheimer somewhere along Llano River. It is, so far as known, a strictly Texan species, and has been in only two or three other stations in that state. It is noted for sometimes making itself an extra pair of leaflets, thus becoming partially five-foliate. The peculiar *Talinum lineare*, handsome *Oxalis vespertilionis*, one or two species of *Menodora*, *Cassia Lindheimeri*, *C. Pumilio* and the black-eyed form of *Enothea serratula* begin to appear near the Colorado River in Burnet County.

While at Llano I set out on a search for *Mollugo cerviana*. This rare and little-known plant was discovered by Dr. Palmer about twelve years ago, for the first time in Texas, near Bluffton, on Colorado River. That station is about thirty miles from Llano. My labor was rewarded by finding a single specimen. Two or three days later I found another individual, and almost despaired of finding more. But I found it subsequently in abundance in another locality. It delights in fine granitic sands, where little else will grow. This species has nearly the flowers of *M. occidentalis*, from which its narrowly linear glaucous leaves will readily distinguish it. These stations in Llano County are the only known Texas stations for this plant. It has, however, been collected in New Mexico and in Arizona. Collectors will doubtless find the species abundant, as I did, along the left bank of Pecan Creek, a little way above the highway bridge, and a mile or so west of North Llano. Little *Dichondra repens* is abundant in Texas wherever I have been. It is called a coast plant. It is found along the coast, but more abundantly away from it. I first met it at Arkadelphia, Arkansas. *Cissus stans*, which, however, seldom stands, and often climbs by tendrils thirty to forty feet high, with *C. incisa*, and *C. Ampelopsis* are found within the range of these observations. The southern Dewberry (*Rubus trivialis*) is also here and westward to the Rio Grande. Its stems are sometimes twenty feet long.

Lampasas, Texas.

E. N. Plank.

Mid-October in West Virginia.

THE Sour Gum (*Nyssa aquatica*) is, perhaps, the most beautiful of trees in mid-October here, yet its glory is fleeting. The earliest of trees to don its garment of brightness, it is the first to lose it, and now stands naked and forlorn, while its less brilliant neighbors, the Oaks, have scarcely lost a leaf. Twin Gum-trees, standing six feet apart on rising ground in the midst of the grove at Rose Brake, made a splendid picture for a few bright sunny days of the second week in October, all the more noticeable from the scarcity of brilliant coloring in the warm dry weather that still prevails. Now the trees are stripped and the ground beneath them glows with scarlet, fast withering to brown. These twin trees are unusually high-colored in October, the leaves turning a uniform bright red. Other Gum-trees in this grove never take on such deep tints, but are, perhaps, even more beautiful, because more varied, with red, orange, pink and green, as the sunlight blends their colors into indescribably lovely effects. Few trees possess so much individuality as these isolated specimens of *Nyssa aquatica*, with their varnished leaves, irregular forms and gnarled and crooked branches. The effect of their fantastic outlines is far more pleasing than the most formal symmetry. To no other tree does the word picturesque more appropriately apply. The individual leaves of the Gum-trees hereabout are almost always marred by the singular little larvæ that prey upon them. Sitting under the trees in late September, I used to wonder at the curious oblong "seeds," as I supposed them to be, that fell whenever a light breeze shook their foliage. Once, to my horror, I found one of the "seeds" endowed with voluntary motion and slowly and awkwardly endeavoring, by a series of galvanic jerks and somersaults, to explore the shawl upon which I sat. A little dark head emerged, and tiny feelers laid hold upon the woolly-surface shawl, and then I cut short the enterprise by taking up the explorer, bed and all, to examine. There it was, snugly tucked between two leaf-blankets, a worm or larva about one-third as long as my little finger-nail. It had preyed upon the leaf of the Gum-tree, and, not content with board, exacted bed and shelter as well from its unwilling landlord. Afterward I found, by holding the leaves up to the light, many an intruder between the upper and lower surfaces eating away the tissues of the leaf and never risking its own precious skin in return. All its active larva-life seems to be spent in this manner from the time it hatches from the tiny egg which the mother moth lays

between the layers of the leaf. Then, when its growth is attained, it carefully eats away an oval portion of the leaf, which encloses its small self and takes no further care. Puff comes a waft of wind and down it tumbles, to await the next chapter

here in the most favorable season; this year only one out of three planted in the spring is alive. Silver Firs suffer much, and some of them are too far gone to be saved when the skies relent. English Yews have died outright of pining for the

Fig. 90.—*Dendrobium chrysotoxum*.—See page 534.

in the story. I have counted as many as five of these oval perforations in one leaf.

Our young conifers continue to dry and brown before our eyes—a discouraging sight. Hemlocks are hard to establish

moist soil and frequent rains of their native land. It is a clear case of nostalgia. But the Deodar or Indian Cedars and our one tiny Cedar of Lebanon are as fresh as when planted in the spring, and a Japanese *Cryptomeria* has taken firm hold

of the rich soil of an old wood-pile, where it was planted, and is in flourishing health.

The Japanese *Retinisporas* are nearly all doing well, while *Kalmias* and Evergreen *Andromedas* have given up the struggle. *Euonymuses* and the Southern *Magnolia* stand the season well, and so do *Hollies* and the beautiful *Mahonias* and the choice *Osmanthus illicifolias*, one of the finest of broad-leaved evergreens.

In the deciduous shrubberies perhaps the most striking plant at this season of the year is *Callicarpa purpurea*. Its foliage is still green and its many clusters of small berries, which are a very unusual shade of pinkish purple, with metallic lustre, are exceedingly odd and pretty. These berries do not lose their brilliancy until late in the winter season, and I do not think they are often eaten by birds.

Yuccas are proving fine plants for a dry hill-side. They are unaffected by drought and are fresh and green at all times. We prefer to plant them in groups away from other shrubs. A few that are allowed to cluster around a large *Arundo donax* form a very attractive group.

Rose Brake, W. Va.

Danske Dandridge.

Plant Notes.

Dendrobium chrysotoxum.

DENDROBIUMS with golden-yellow flowers are always admired, especially in this group, when the flowers are borne in clusters. The subject of the illustration (p. 533) is in the collection of E. V. R. Thayer, Esq., of Lancaster, Massachusetts, and is one of the largest and best examples of the plant in this country. It carried twenty-four handsome spikes, crowded with blossoms, which remained in full beauty for four weeks. Its flowers appear during the early spring months, and, consequently, make a most useful plant for exhibiting. The glowing yellow color of its blossoms makes a delightful effect when arranged with graceful Palms and other plants with ornamental foliage.

Baskets or pots will suit the cultural requirements of this plant, although baskets are preferable, since an abundance of air is essential during its period of growth, enabling the compost to dry out more quickly, and, therefore, be less liable to become stagnant. Good fibrous peat, with very little sphagnum and free drainage, is the best compost. During active growth it enjoys a temperature of sixty to sixty-five degrees. A few degrees higher with sun heat will prove very beneficial.

A. Dimmock.

New or Little-known Plants.

Halesia tetraptera Meehani.

THIS seedling form of a well-known plant is figured on page 535 of the present issue, as it is not only interesting as showing a possible range of seminal variation, but of considerable value as a garden-plant. Its history is best told by Mr. Meehan himself, who has communicated to us the following information:

"Formerly we had only two trees of *Halesia tetraptera* from which we collected seeds for our nursery work, one in Germantown, on the Upsala estate, and one in Laurel Hill Cemetery. Our own history credits the seed from which the variety was raised to the Germantown plant, though I am willing to admit that it may have been collected in Laurel Hill Cemetery. In any case, however, there is not the slightest possibility of any hybridizing with *Halesia diptera*, the only specimen of which in this region was the small plant in Bartram's gardens, ten miles away.

"In passing the seed-beds one day I thought I noticed an Apple-tree growing with the *Halesias*. This attracted my attention to this curious plant, which was taken up and preserved. The flowers are no less interesting than the foliage and habit, as there is no trace of the narrow tube-like base peculiar to the corollas of *Halesia tetraptera*; the corolla is completely saucer-shaped, and Professor Gray, after examining a flowering branch, remarked that

if it had been found wild one might reasonably suspect a new genus.

"Though the sexual organs seem perfect and the anthers abundantly polleniferous, the plant is barren. Once I found two seed-vessels; they were very small, subtrotund, and strictly four-winged, as in those of *Halesia tetraptera*. The habit of the plant is wholly unlike its parent; the head is round and bushy, looked at from a distance precisely like an Apple-tree. At the present time the original plant is about twelve feet high and the head twelve feet across, the trunk being six feet high and fifteen inches around. My men, feeling some distinctive name for nursery purposes necessary, have distributed this plant as *Halesia Meehani*. I dislike Latin names for garden varieties, although this form might have sprung up in the forest as well as in my garden, and it seems to me that if the practice is ever justifiable it is in the present case."

Halesia tetraptera Meehani differs from the ordinary form in habit; the flowers are smaller, with a short calyx-tube and a cup-shaped corolla without the narrow base of that of the species, and are borne on pedicels which rarely exceed half an inch in length, while those of *Halesia tetraptera* are often three times that length. The leaves of the variety are thicker, distinctly rugose, pale, and on young vigorous plants often conspicuously glandular-serrate.

Foreign Correspondence.

London Letter.

CYCADS.—A lecture on Cycads by Mr. Carruthers, the principal botanist of the British Museum, was a special feature in the programme of the Royal Horticultural Society last Tuesday, the other attractions being a competitive exhibition of fruits and collections of new and interesting plants. Although Mr. Carruthers talked exclusively of the botanical features of his subject, he said a great deal which would interest the cultivator. The position of Cycadaceæ in the botanical system is generally supposed to be close to Palms, but, as a matter of fact, they are very nearly related to the Coniferae, a relationship which their floral organs conclusively shows, the cones of Cycads being very similar to those of conifers structurally as well as superficially. In all other respects, however, the Cycads differ very widely from the conifers, their thick, rarely branched trunks bearing broad crowns of pinnate, sometimes spinous leaves, which are folded involutely, when young, like the leaves of a Fern, and the habit of producing their cones in the centre of the crown of leaves marking them out distinctly not only from conifers but from all other natural orders. There are some anomalous genera among the Cycads, for instance, the Australian *Bowenia*, with an irregular fleshy root-stock, from which spring elegant bipinnate leaves a yard across on stalks three or four feet high; this is a beautiful stove-plant when well grown. *Stangeria paradoxa*, the great Fern puzzle, has leaves exactly like those of a *Lomaria*, and a fleshy Turnip-like stem. It is a native of South Africa, where it was found by a German collector, and named by Kunze, *Lomaria eriopus*. But the eminent pteridologist, J. Smith, curator at Kew, doubted its being a Fern, and about forty years ago a plant at Kew flowering, it was figured under its present name in the *Botanical Magazine*, t. 5121.

The geographical distribution of the Cycadaceæ is remarkable. They are most abundant in Africa, and they occur in many parts of India, the Malay regions, Australia, Central America, Florida, the West Indies, China and Japan. The tallest are the *Cycases*, stems of which have been seen forty feet high, and the smallest is the little Floridan *Zamia pygmæa*, or *integrifolia*, as it is sometimes called. In the geological history of plants Cycads appear to have occupied a prominent position among the very first of the dryland vegetation—that is, of the Devonian or Mesozoic Age. They then appear to have been world-

wide in their distribution, representatives of them having been found as far north as Greenland. They are said to be the remains of an otherwise extinct vegetation, and, as Dr. Masters remarked in the discussion, the existence of living representatives of Cycadaceæ is quite as startling a fact in botany as living examples of *Ichthyosaurus* and *Megatherium* would be in zoölogy. *Cycas* is found in the East Indies and Madagascar, *Encephalartos* and *Stangeria* in Africa, *Bowenia* and *Macrozamia* in Australia, *Zamia*, *Ceratozamia*, *Dioon*, and *Microcycas* in America

AND FOREST to the merits of some of the Cycads as garden-plants. They are more in favor in Belgium, France and Russia than in England. I know no more noble plants either at Kew or elsewhere than the grand specimens of *Encephalartos*, *Cycas*, *Macrozamia*, *Dioon* and *Ceratozamia*, which are to be seen in the few gardens where Cycads are in favor. A remarkable character in Cycads is that of exceptional vitality in their stems. The plants may be cut down and their heads put in as cuttings with safety, and although they do not branch, as a rule, yet if they

Fig. 91.—*Halesia tetraptera* Mehani.—See page 534.

and the West Indies. Mr. Carruthers stated that *Bowenia* in Australia and *Stangeria* in Africa are totally unlike any other vegetable forms among which they grow; there is no plant known either in botany or geology which links them with the chain of vegetation as at present known. He asked the pertinent question, "Are these two plants the remains of an otherwise extinct race, or are they newly evolved?" The exceptional interest of Cycads is not the only claim they possess to the notice of horticulturists. I have lately drawn the attention of the readers of GARDEN

lose their central bud they will sometimes develop one or several buds lower down the stem. I have seen a *Cycas* stem, the top of which rotted, afterward produce three lateral buds, which finally developed and grew into three separate plants. Imported stems have been known to remain quite dormant for more than three years, and then push into vigorous growth and flourish.

NEW VARIETIES OF *CORDYLINA AUSTRALIS*.—This is one of the most variable of New Zealand plants, and there are many forms of it already in cultivation here. Mr. Elliott,

of Christchurch, Hampshire, recently exhibited some new varieties which promise to eclipse most of the older kinds as decorative plants. Among them are *Aureo-striata*, narrow and rather short in leaf, with lines of deep yellow on a green ground, and more or less spirally twisted; *Nobilis* has distinct parallel lines of brown not unlike the older *lineata*, but the leaves are shorter and broader; *Compacta nana* accords with its name, and is a pretty little plant, likely to become a favorite for table decoration; *Elegans* has linear arching leaves, and *Lusiformis* is another elegant variety; *Rubra* has rich bronzy brown foliage and is a handsome plant. It was awarded a first-class certificate by the Royal Horticultural Society. We believe these are all selections from seedlings raised in New Zealand.

NEW CHRYSANTHEMUMS.—There were four *Chrysanthemums* selected for certificates from the large number of new seedlings shown this week: Mrs. C. Myers (Owen), a broad-petaled, large-flowered, white Japanese; Baron Hirsch (Owen), a reddish bronze flower with golden reverse, of the incurved section, with broad substantial petals. It is a large and promising variety for the exhibition-table; William Seward (Seward), a Japanese variety, with the color of *Cullingfordii*—that is, brownish crimson, with buff reverse. The flower is large and of good form. It was generally voted to be one of the best of the newer seedlings. *Beauty of Exmouth* (Godfrey), a beautiful white Japanese variety, said to be the result of a cross between *Avalanche* and *Stanstead Surprise*. The flowers are very large, globular, the petals broad and curled and pure ivory-white. The plant grows about five feet high, and the flowers are developed from October to January.

NEW ZONAL PELARGONIUMS.—Mr. Cannell has produced several varieties of merit this year. Among those exhibited for certificates this week were *Madame Bondeville*, of French origin, remarkable for the size of its flower-heads and for the very pleasing color of its flowers, soft salmon, with a distinct marginal line of rosy pink. *Raspail Improved* is a genuine improvement on the original; it is larger in truss and much larger in flower than the popular market variety *Raspail*. The flowers are rich scarlet, and some of them measure over two inches across. *Double New Life* is a remarkable sport of the third generation from *Vesuvius*, obtained twenty-five years ago. Out of *Vesuvius* came *Wonderful*, which yielded *New Life*, a single-flowered variety with white flakes or stripes on the petals. From this has sprung *Double New Life*. It is only semi-double, but its looseness and the white flakes on the petals make it attractive. These received certificates.

MELON BEAUTY OF SYON is a new seedling which received a first-class certificate this week from the Royal Horticultural Society. The gardener at Syon, Mr. G. Wythes, has taken special interest in the culture and improvement of the Melon, and he is to be congratulated on having raised one which promises to become a general favorite. It was raised from *Hero of Lockinge* and another, and has round, medium-sized, yellow-netted fruit, smooth, with scarlet flesh, melting, juicy and of first-rate flavor. The members of the Fruit Committee were unanimous in its praise. It will, no doubt, be better earlier in the season than in the middle of October.

Cultural Department.

Plants for Summer Decoration.

MUCH has been said against the practice of bedding out, but, after all, when the proper plants are used we can secure effects in this way which are not obtainable in any other, and as stock-plants are now in their winter quarters or protected and made secure, it is worth while to name some of the plants which have proved most useful during the past year, so that they can be propagated during the winter in sufficient numbers for our purposes next season. It is well to secure a considerable variety, if only to break the monotony, of the too prevalent *Coleus* and *Geraniums*.

Among the species most worthy of cultivation is *Acalypha*

tricolor, a plant of strong growth with ovate-acuminate leaves, coppery green and beautifully blotched and colored with red and crimson. Our hot summers suit it admirably, and it should be planted in the very warmest spot possible, and in the full sunshine. It is easily propagated by cuttings, but where the stock is limited the old plants must be preserved for use. It does not lift well, and a little extra attention in this particular will be well repaid. It is a stove-plant, and, therefore, must not be subjected to a low temperature when taken from the ground. The young succulent growth of the tips of the branches will answer for cuttings, and large plants, cut back root and branch, and laid on a bench where there is gentle bottom-heat will soon break, and as fresh growth and roots are made the plants should be potted and kept in a warm house, and abundant cuttings will be afforded during the early season of the year.

Another useful plant is the variegated form of *Sanchezia nobilis*. It is large, with leaves of intense green, their mid-ribs and veins heavily margined with gold and yellow, so that the entire plants can well vie with the popular *Croton* when used in summer decoration. It grows more freely, however, and is more easily propagated than *Crotons*, and stock can be raised in a short time. *Crotons* themselves have formed such striking features in the public parks of late that their use in private grounds is sure to become extensive. In diversity of color and form of foliage they are most attractive. They, too, delight in full sunshine and rich soil, and copious supplies of water during hot weather. Large plants are most effective, but they require time to attain size. Smaller specimens will be satisfactory, but instead of crowding them it is better to use some dwarf plants to cover the surface of the bed, so that the individual beauty of the *Crotons* can have full opportunity to display itself.

Very graceful and charming for summer use is *Phyllanthus Roseo-pictus*. The variegation is exceedingly rich, no two leaves showing precisely the same markings or tints. Many of the leaves are bright crimson, which is also the color of the stem during the early stages of its growth. Some are a light cream color tinted with a delicate blush. Others, again, have a dark bronzy hue shaded with crimson, while some are dark green with blotches and spots of rose. Others are tricolored, being white with different shades of rose and green. A plant six or eight feet high and furnished to the ground, is a magnificent sight. Smaller plants can be used as centres of beds with an undergrowth of *Altenanthera aurea*, which makes a pleasing combination. When planted out, small plants grow rapidly. They are multiplied by cuttings from the shoots and roots, the latter being preferable.

Grevillea robusta makes a beautiful specimen plant on account of its Fern-like foliage. In a group also it is well placed in the centre of a bed. Plants raised from seed early in spring will usually be large enough to plant out the same year, but fall-sown seedlings are preferable for specimens. Older and larger plants are very ornamental where space can be afforded for wintering them, but as they grow rapidly and attain a height of from eight to ten feet the second year, it is not necessary to winter very large plants. The same is true of *Eucalyptus globulus*, which is most effective either as a specimen or in a clump, since its glaucous blue foliage is very striking among deeper hues.

Musa Ensete and *M. Martini* are both desirable the first year from seed which is sown early in spring. Their foliage is short and sturdy, and is not so liable to get broken by heavy storms as is that of older plants. The best plants I have seen grown were set in heavy soil. *Papyrus Antiquorum*, whether treated as an aquatic or as a border plant, makes magnificent groups, its tufted blooms rising to a height of eight feet. It delights in a rich moist soil, and endures the weather better in a bed or border than when submerged in water. Planted in a mass with a border of *Caladium giganteum* the effect of the light and dark foliage is very striking. Seeds sown very early in the season and kept on growing will produce seedlings suitable for planting out the same year.

Very desirable, although too rarely seen, is *Cassia corymbosa*. Its beautiful yellow flowers are produced in abundance all the season until frost. As soon as the foliage dies it can be pruned back severely, when plants may be lifted and kept in a cold place through the winter. It can be easily raised from seed, however, although it does not flower, as a rule, until the second season. The Coral Tree (*Erythrina*) is a useful companion to the *Cassia*, and succeeds well under the same treatment. *E. Hendersoni*, which bears abundant bright scarlet flowers, is readily raised from seed, and one of the very best.

The Rubber Tree, *Ficus elastica*, and its variegated form, must not be omitted from this list of plants for summer deco-

ration on account of its dark green glossy foliage and bright crimson sheaths, which are much brighter than when grown within doors. It endures the weather well and can be lifted without injury. Now is a good time for propagating it. The main shoots should be girdled so as to check the flow of sap and form a callus. If moss is tied around and kept moist, roots will put forth, and with a little attention a good plant will be formed before it is severed from the stock-plant. Shoots may also be taken off, and leaves with eyes that are started, placed in a propagating-frame with bottom heat, will make plants for next season.

New Zealand Flax (*Phormium tenax*) and its variegated variety are very serviceable in exposed places. Their long sword-like leaves are quite distinct when associated with other sub-tropical plants, and are never beaten or broken by heavy storms or high winds. This is also a useful plant for the greenhouse or living-room. Solanums and Wigandias are rapid-growing and ornamental, but they need to be set in a sheltered place or they are soon damaged, since their growth is succulent. No decorative plant has made more marked improvement than the Cannas. The variety, Madame Crozy, with its dazzling brilliancy, is almost painful in a mass, but where planted in small quantities and relieved by the bronzy green foliage of other varieties, it is magnificent. A single plant in a mixed border is also very effective, and so are specimens in greenhouses or conservatories. It flowers perpetually, and can be had in bloom the whole year round. Other equally good and distinct varieties have made their appearance this season and promise to be valuable. Among them I should select Alphonse Bouvier, a strong-growing sort, three and a half feet high, with deep green foliage and tall spikes of rich scarlet-vermilion flowers, which are very large and distinct. J. D. Cabos is another striking novelty, which grows strongly to the height of four feet and has rich purplish foliage. Its flowers are large and round, of a rich apricot color, with deeper shadings. Cannas are readily raised from seed, which will flower the first season, and a large percentage of good flowers are produced from the seed of Madame Crozy.

Cordyline indivisa makes a very graceful and serviceable specimen, and, when small, is an admirable centre for a vase. Its leaves are long, tapering, light green, and not readily broken by high winds even in exposed positions. Plants are quickly procured from seed, and soon grow to specimen size, as they make rapid growth when planted out during the summer. They can be easily lifted, too, and kept in the greenhouse during the winter. They do not need pots in proportion to their size, as many other plants do. When lifting most plants in fall it is desirable to put them into as small pots or tubs as will conveniently contain the roots without bruising them. The preservation of a good ball of roots, however, is necessary for all those that are annually planted out and lifted.

Dongan Hills, N. Y.

Wm. Tricker.

Foliage-plants.

IN the case of warm-house plants at this season more attention is needed to secure the proper conditions of temperature and moisture than during the summer; as the days shorten the growth of such plants will be slower, and they are thus less able to withstand extremes of treatment. Comparatively little potting will be needed among this class of plants during the next two or three months, except it may be in the case of some small specimens that would be likely to suffer before the time of the general repotting in the spring. Even in such instances it is advisable to give only a small shift, for overpotting is doubly dangerous to tender-rooted subjects during the early part of the winter. Watering and syringing should be done early in the day, for too much moisture on the foliage will soon injure it, though when strong heat is applied after the nights become colder, it is a good practice to damp down the walks and under the benches in the afternoon, to prevent the atmosphere from becoming too dry.

The attacks of insects must be watched for with strict attention also during the winter months, for with the partial cessation of syringing such pests as red spiders and thrips are very likely to appear on *Dracænas*, *Cordylines*, *Crotons* and *Diefenbachias*, and, if unchecked, will soon ruin the foliage. Tobacco-water is the most effective remedy for these troubles, and in a conservatory is less objectionable than fumigating, besides being more effective, with red spiders at least. If this pest becomes plentiful on any particular plant, it may be removed by giving a dip in tobacco-water to which has been added some sulphur, the strength of the wash being proportioned to the kind of plant, for the tobacco-water will injure tender foliage when used too strong.

Several of the prepared insecticides are also useful preparations for this purpose, especially for small establishments where the limited quantity of such mixtures required makes their cost appear less formidable. But if any considerable quantity of insecticide is needed it is more economical to use the home-made remedies, and among these the tobacco-water and solution of whale-oil soap are among the most satisfactory. For some extreme cases the kerosene emulsion is very effective, but this must always be used with judgment, or the result will be disastrous.

The propagation of various foliage-plants can be carried on during the winter, provided sufficient heat can be had for the purpose. Among these *Crotons* and *Ficus* may be included, the first-named rooting readily at any time in a warm house. With generous treatment there will be nice-sized plants for bedding out in June. There is also little difficulty in rooting *Ficus* cuttings, especially about January. The safest method is that of topping, by means of an incision in a shoot, some three or four leaves from the tip, and binding some damp moss around the cut. Under favorable conditions these tops will send out roots in two or three weeks, and can then be removed from the parent plant and potted. Such cuttings naturally make more shapely plants than those struck from a single eye, and the tops can be rooted at any season of the year without difficulty.

Some of the slender *Aralias*, like *A. Veitchii*, *A. elegantissima*, and *A. leptophylla*, can also be worked during the winter and spring, using for a stock either *A. reticulata* or *A. Guilfoylei*, as the first-named species are very slow rooting from cuttings, and will grow away more freely when grafted. The stocks for this purpose may be supplied either from root or top cuttings, cleft grafting, if neatly done, being the most satisfactory method for this operation.

The tops of *Cordylines* and *Dracænas* may also be rooted in the manner recommended for *Ficus*, making by far the finest specimens, as they have large leaves, extending to the pot, if properly grown, beside showing more color than those that have been potted on from small plants.

Holmesburg, Pa.

Wintering Strawberry-beds.

THE proper care of Strawberry-plants during the cold weather is an important item in the cultivation of this fruit. They may live through a very low temperature, and yet suffer seriously in vigor and usefulness; a smaller, inferior and later crop is sure to follow needless exposure. The extent of this damage depends, of course, on the severity of the winter and the degree of exposure. In the northern states a temperature not much below the average is liable to make a clean sweep by killing the plants outright. Even in this latitude, and in ordinary winters, I find the loss to average one-fourth, and wherever the thermometer is liable to drop ten degrees below freezing winter protection will pay well. Numerous substances may be used to protect the plants; some better than others; almost any better than none. At the south we never think of anything but pine-needles, or pine-straw, as we call it. Not only does the resinous nature of the pine-straw tend to repel insects which might possibly take refuge under the covering in winter, but it is an excellent non-conductor. It is also, from mechanical reasons, an ideal protector. Its shape and size render it easy to apply evenly and rapidly. The needles are so small that even the hardest wind is apt to pass through the mass without any serious displacement, while the same openness allows the passage of sufficient air to prevent smothering even where the cover is deeper than it should be. I have had plants to survive an accidental covering of three feet, and that, too, where the pile of straw lay for four months. I need hardly say that such a deep covering would be neither practicable nor safe, one inch of this kind of covering being sufficient even in a cold climate.

Pine-straw not to be had, my next choice should be corn-stalks, laid uncut and evenly over the bed in the direction the rows run. As they lie much more open than straw, a depth of one foot would be about right. Where neither of the above are procurable, recourse is generally had to hay or wheat or oat straw. The main objection to these is that they are all easily blown off. Some seek to prevent this by chopping it very short, which, according to my experience, is no remedy at all. The separate particles are still so much larger in proportion to their weight than pine-needles that they are apt to take wings on gusty days. I should much prefer to apply the straw whole, and anchor it by means of poles or some such weights laid on top. Even earth might be used to hold the straw, provided a little care was taken in its application and removal. It need not be either deep or continuous, but

only in small piles as far apart as the length of the straw will admit.

Coarse stable-manure possesses a natural warmth beyond other substances, besides being an excellent fertilizer. Yet it is more apt to smother plants than either of the others, if carelessly applied. But even when very fine, a uniform application half an inch deep would be safe, and can be left on as a mulch through bearing time, the weeds being kept down by hand. When an inch of pine-needles or grain-straw was used, quite two-thirds should be removed from over the plants in early spring and left between the rows. Should the alleys between the rows be too narrow the surplus straw must be taken off the bed and piled elsewhere.

Ordinary forest-leaves are often successfully used, weighted down like grain-straw. Even chips or sawdust are better than nothing, provided they are not suffered to accumulate on the bed to the detriment of the soil. In a moderate climate, say where the mercury keeps above ten degrees, Fahrenheit, evergreen bushes or boughs would be equal, or possibly superior, to pine-straw.

In short, there are so many things available for this purpose that no gardener, unless he is woefully lacking in energy and ingenuity, need fail to find some of them. Anything that protects without smothering will answer. A safe rule is to apply nothing too deep to prevent a slight freezing of the ground in severest weather. The proper time to apply is as soon as the ground freezes an inch deep. Rake off the surplus before it is time for the plants to start into growth. Here I find that from December 1st to March 10th to be the best average dates to cover and uncover, respectively.

There is another very good use to which this straw, etc., may be put. As it lies between the rows after being drawn off the plants in spring, it can easily and quickly be drawn back on them to save the blooms from frost. In case of protracted cold, it can safely be allowed to remain for three or four days without damage to the plants. Its removal is also a small matter. Even where cold snaps should occur repeatedly the raking on and off the straw would consume only a few minutes each time, and be many times repaid by a crop of fine early berries, which would otherwise be destroyed.

Forests in California.

To the Editor of GARDEN AND FOREST :

Sir,—The subject of the preservation of Californian forests is seldom discussed without some reference being made to the injury wrought by roving bands of sheep, and by the fires which follow in their wake. Throughout the high Sierra sheep are pastured only in summer, and find winter feed in the foot-hills and valleys. In the high mountains the land belongs to the Government for the most part, and the sheep are nomadic. Young trees are killed by browsing, while, by accident or design, fires start which sweep over vast areas, killing the young conifers and much large timber as well.

I only allude to the connection between sheep and forestry in the Sierras to emphasize a curious paradox in another section. Lying from the sea-coast back for fifty to one hundred miles, and reaching in California from San Bernardino on the south to the Oregon boundary and continuing through Oregon and Washington, the Coast-range is a vast mountain system enclosing numerous valleys. In northern California a belt of coniferous trees, mostly Redwood, lies next to the sea-coast, and in Oregon and Washington the Coast-range is covered with Spruce and Fir. Outside of the Redwood region and the groves of Yellow Pine, of comparatively small area, the Coast-range in California is a region of Oaks and other deciduous trees, with large tracts of grassy slopes, and equally large areas of low, dense brush, locally called Chemical and Chaparral.

This whole mountainous section is devoted to sheep. The land, or enough to control it, is owned by the sheep-owners in tracts large enough to carry flocks of from 1,000 to 20,000 head, which range over the same country throughout the year. Now, it is a matter of common remark throughout this section that the brush is encroaching rapidly upon the open slopes or grazing-land. That it should be so seems strange, flatly contradicting, as it does, our preconceived ideas of what the effect should be. It would seem that in the ages past the timber would have covered all suitable areas. To understand why we have this result we must study conditions. Before the white occupation all of these open slopes were covered in summer with a luxuriant growth of grass. Wild

Oats grew waist-high, and other grasses in proportion. Fires were started by natural causes, or by the Indians, who fired the grass to drive game from cover or to open up the brush for future hunting; and these periodical burnings had such a great heat as to kill trees or shrubs of most sorts in the grasslands and to keep down the hardiest sorts.

When these mountains became private property and sheep were run on them, the luxuriant growth was kept down. Many natural grasses are killed out and replaced by foreign grasses. I have seen the entire range of grass change twice. Sheep-trails and grass eaten to the ground stop the spread of fires, and then, too, there is not such a mass of tinder to make so intense a heat. Grass is the sheepman's capital, and he carefully guards against brush or grass fires. The sheep can by browsing do little injury to the Oaks, and will scarcely touch the Laurel, Manzanita or Madroña.

As a result, we not only find the brush and woodland encroaching on the pasture, but the dense thickets of brush are becoming woodland by shading out the weaker growth.

Late Flowering of Jackman's Clematis.

To the Editor of GARDEN AND FOREST :

Sir,—Passing along a street in Marblehead, Massachusetts, I was surprised to see this morning (October 29th) a splendid specimen plant of Clematis Jackmani that had been trained above the second story of a house, and which presented a mass of most gorgeous bloom on all its terminal shoots. Without doubt, there were from twenty-five to thirty perfect flowers, and of more than ordinary size individually. That this gorgeous effect would be possible at this date would ordinarily seem quite incredible, but is illustrative of the unusually late autumn which we are experiencing.

Reading, Mass.

J. Woodward Manning.

Periodical Literature.

Citing as its authority Mr. C. W. Hayes, who not long ago explored the Yukon District of Alaska, the *Popular Science Monthly* for November says that in the interior plateau of the Cordilleran and St. Elias regions "surface degradation is greatly retarded by the luxuriant growth of moss, which covers practically the entire surface of the country. The annual precipitation is largely confined to the winter months, and the water from the melting snow is held by the sponge-like moss, which remains saturated throughout the short but hot and dry summer. Thus, with a rainfall which in lower latitudes would condition an arid region, a large part of the surface is swampy, quite irrespective of slope—that is, wherever the material composing it is sufficiently compact to become impervious to water on freezing. On account of this slow and imperfect surface drainage, the slopes are not cut into the ravines and arroyos so characteristic of arid regions."

Last year Mr. Frederick Le Roy Sargent published a note in the *Bulletin of the Torrey Botanical Club* with regard to a Linden which did its best to profit by an injury to its trunk by throwing out adventitious roots to feed upon the decaying wood within. This has called forth accounts of similar instances of abnormal growth from several other observers, and Mr. Sargent now publishes them in the *Popular Science Monthly* for November in an article called "Economical Trees," in which the foregoing and a number of new examples are brought together in an interesting comparison. Several good illustrations accompany the paper, the most remarkable of them showing the trunk of an old Mulberry which stands at Thomasville, Georgia. Of this Mulberry, its owner, Dr. T. S. Hopkins, writes: "I have had an intimate acquaintance with this old tree for thirty years. I do not know how old it was when I first knew it. Some fifteen years ago it was uprooted by a storm. I carefully amputated its limbs and re-erected its body. It lived and improved, and to-day furnishes as much shade as it did before its fall, and the surgical operation made necessary by it." Mr. Sargent adds that "in point of size, extent of decay and the number and thickness of its adventitious roots, it would seem to be much the most striking example of an economical tree thus far described. The trunk is now about three feet or more in diameter, and so much decayed as to leave merely a shell of no great thickness. The adventitious roots are some of them as thick as a man's arm. They all ramify through the disintegrating heart of the tree, and the longest of them appear to reach the earth. Besides saving from waste the products of decay, these roots must add considerable strength to the weakened trunk. This feature is,

perhaps, all the more significant in view of the Mulberry's near kinship with the Banyan-tree, which makes such wonderful mechanical use of aerial roots." The picture shows some of the roots of the Mulberry crossing the huge cavity in the trunk like mammoth harp-strings.

Exhibitions.

The New York Chrysanthemum Show.

THE great amphitheatre of the Madison Square Garden is a place of surprising changes, and there is no change during the year more cordially welcomed than that which converts it into a maze of Chrysanthemum blossoms. Under the auspices of the New York Florists' Club, the Madison Square Garden Company opened the usual fall exhibition on November 1st, with a schedule of prizes valued at nearly seven thousand dollars, an amount which should have brought on an interstate competition, which would be sure to prove interesting. There was no lack of material, however, though the competition was mostly confined to local growers. The broad oval was filled with masses of flowers. As one entered the Garden and passed a great mound of decorative plants, contributed by Messrs. Siebrecht & Wadley, the foreground was seen to be filled with trained plants, beyond which, surrounding a fountain with a large basin, were covered tables, on which were displayed the cut flowers for competition. The borders of the oval were banked with great numbers of plants in small pots grown to single stems, which seem so popular among the growers. Beyond the tables a mass of Palms marked a floral booth in white, which was in striking contrast to the gay central booth of last year. The large vases of flowers, which were the striking feature of the last show, were duplicated here in great numbers, and even more bold effects were seen with enormous bowl-shaped vases, each containing twenty-five or fifty blooms. We doubt if any nobler display of the Chrysanthemum at its best has ever been made at any exhibition.

A half-dozen large Chrysanthemum-flowers in a tall vase of suitable size is such a satisfactory object that every one does not realize that a single bouncing bloom is a difficult subject to dispose of satisfactorily, owing largely to the fact that the flower has no surplus foliage as a foil. A board of Chrysanthemums is not an aesthetic object, but has certain advantages from an exhibitor's point of view. But, as the flowers have grown in size, it has been felt that an effort should be made to show them more informally and in ways which would make them more attractive, if possible, to the great flower-loving public.

The New York Florists' Club is a progressive body and deserves great credit for its bold departure in devoting a large share of the prize money to exhibits of cut flowers shown with long stems and arranged in uniform vases as supplied by the management. These vases, moulded in a handsome pattern of clear glass, were about two inches in diameter, with ample bases, and a foot high. Taking the flowers as units, the arrangement is of great merit, but such vases need space for effectiveness, and it will be necessary to devise some arrangement of the various collections of twelve, twenty-four and forty-eight, and to show the individual vases and flowers. Some simple device, like a table of medium height with terraces or steps, would possibly add very much to the individual and general effect, especially if the different collections were separated by a few small foliage-plants. The specimens were to be seen in tens of thousands, and, on the average, distinctly superior to those shown last season. Not only was the average of the flowers better as to finish and size, but they were notably, with few exceptions, of firmer substance and remained in good condition longer than before. The competition was keen in cut flowers, and all the classes were well filled.

The cup offered by the GARDEN AND FOREST Publishing Company for the best vase containing six blooms of one variety was awarded to Peter Henderson & Co. for a vase of the Golden Wedding, a variety of Japanese origin, which is the sensation of the season. The flowers are of the very largest size, yet not coarse; the form is perfect, the petals gracefully incurving somewhat irregularly. The color is a clear golden yellow. A mammoth vase furnished with fifty flowers of this noteworthy variety also gained the silver cup offered by Mrs. W. Bayard Cutting. The John Eyerman silver cup, for the best six blooms of pink, was awarded to J. Simpkins for a vase of Mermaid. The silver cup of Peter Henderson & Co., for a vase of twenty-five yellow flowers, was awarded to J. Brydon, of Yarmouthport, Massachusetts, for a fine mass of

W. H. Lincoln. The Dailedouze Brothers' prize for the best six blooms of any variety introduced in the spring of 1892 was taken by Julius Roehrs, for fine blooms of Maria Simpson, a flower in the way of Eldorado. The principal prizes for classes of cut blooms were taken by Ernest Asmus, Dailedouze Brothers, Pitcher & Manda and Julius Roehrs.

An interesting exhibit was brought out in the competition for the best twelve vases with six flowers of one variety in each vase. The group which took the prize contained Miss A. Swann, Harry May, Roslyn, Minnie Wannamaker, H. Cannell, Lillian B. Bird, Eda Prass, Colonel W. B. Spaulding, Kioto, H. E. Widener, J. H. White, Ada Spaulding, and the plants were shown by F. T. Underhill, Oyster Bay, Long Island. The prize for the best twenty-four Japanese varieties, shown on boards, was awarded to Ernest Asmus with the varieties Edward Hatch, Dr. Callendreau, H. E. Widener, Miss Bertha Robinson, W. H. Lincoln, Exquisite, Mrs. E. D. Adams, Mrs. J. Thomas, Viviani Morel, Ivory, Volcano, Mrs. Governor Fifer, Mrs. Irving Clarke, Golden Gate, Domination, Mermaid, Jessica, Waban, Cochinella, Edward Hitzeroth, Mrs. J. N. Gerard, Ed. Molyneux, Minnie Wannamaker, Hicks Arnold.

A vase given by J. H. Taylor was awarded to Dailedouze Brothers for the best flower in the show.

Plants in trained specimens, standard plants, and plants grown to single blooms, were shown in large numbers, but were without special feature. For these the principal prizes were taken by Pitcher & Manda, Julius Roehrs, Ernest Asmus, T. H. Spaulding. A special prize, a silver cup, offered by James Dean, was awarded to T. W. Hatfield, gardener to Walter Hunnewell, Esq., of Wellesley, Massachusetts, for the best plant exhibited. This was a well-grown and flowered plant of Mrs. Alpheus Hardy.

On Thursday seedlings were exhibited in great numbers; but, although the flowers averaged unusually good, there were no striking advances or departures from well-known types, and few new varieties, indeed, which a Chrysanthemum society would care to certificate as superior in any respect to those already in cultivation. As varieties multiply it becomes more and more necessary to be cautious about scattering such honors as first prizes at a great exhibition with too lavish a hand. The first prize for the best pink seedling, for example, might mean very little if there were only two or three flowers of that color in the competition, and it means still less if the flower so decorated is not a true pink after all. Among the white varieties, W. G. Newett; among the yellows, Mrs. F. L. Ames, and among the pinks, Wm. Plumb, attracted notice. The principal prizes in this class went to F. S. Waby, Pitcher & Manda, E. G. Hill & Co., F. D. Underhill and J. N. May.

On the last days of the exhibition, the large vases and baskets in which flowers with long stems were arranged with other foliage, were striking features. These large vases, set on draped pillars or pedestals, often contained a hundred flowers, and many of them were very effective. In some, however, the mistake was made of mingling with the bold flowers Adiantums and other plants of delicate foliage. Several dining-tables were also shown dressed with Chrysanthemums and various kinds of foliage, but in almost every case the decorations were too profuse and looked burdensome.

The cut Roses were unusually good, and if one can judge by the interest manifested by the visitors, the Rose held its own with the Chrysanthemum. The comparatively new Rose, Madame Testout, was shown in admirable form by Ernest Asmus. The flower is a clear pink, which lights up beautifully, and it has an air of refinement and distinction which is quite captivating. The Kaiserin Augusta Victoria is a new white Rose with exquisite Tea fragrance, and is looked upon as a strong competitor of The Bride. Another new Rose shown was Bridesmaid, a sport from Catherine Mermet, and another still was John Burton's American Belle, a sport from American Beauty and a little lighter in color. Mrs. William C. Whitney is a seedling pink Rose, with long well-formed buds, raised by Mr. John N. May. Of the older Roses Meteor was conspicuous, its deep color being rare at this season, and this, with its long stems and good foliage, makes it very desirable. Madame Cusin was abundant, and is popular on account of its good color and keeping quality. Madame Watteville and the old Perle, still unexcelled among the yellows, were also noteworthy where all were good. The chief Rose prizes were won by F. R. Pierson, of Tarrytown; Ernest Asmus, J. H. Taylor and John N. May.

Notice of the Carnations, Cannas and other plants must be deferred, but it may be said that the flowers throughout were worthy of the exhibition, which seems to have become one of the established institutions of the city under the happy co-operation of the Florists' Club and the Madison Square Garden Company.

Notes.

In the Palace Gardens at Ely, according to the *Gardeners' Chronicle*, is a Plane Tree which measures nineteen feet around the stem at its smallest part, six feet from the ground, and from the stem to the branches, on either side, fifty feet. It is about one hundred feet high.

Among the German exhibits at the Chicago Fair will be a mediæval village, to be built on the Midway Plaisance under the auspices of the Deutsche Bank of Berlin, which will show the rural architecture, the home life of the peasants, and the household industries of the selected period.

We have received from Mrs. Dandridge leaves and fruit of the plant which she had purchased for *Elæagnus longipes*. It is a Japanese species, which is called in the Arnold Arboretum *E. umbellata*. The fruit has somewhat the flavor of *E. longipes*, but it is much smaller and matures much later.

Celastrus articulata, the Japanese relative of our native Bitter Sweet, *C. scandens*, is unusually beautiful this year, perhaps owing to the lateness of the season. Our plant has the advantage in habit, since the flowers appear at the end of the young branches, instead of being sessile in umbels at the axils of the leaves, as in *C. articulata*, so that the fruit is hidden by the foliage until it falls. The fruit of the native plant, too, is a trifle larger, but just now the color of the Japanese species is brighter than that of the other.

Complaints are heard from all parts of the north Atlantic states about the parching drought. In many cases the springs and wells have dried up, and it is hardly possible that the ground can be well supplied with water before freezing weather arrives. Under these circumstances it will be a trying winter for trees, and especially for evergreens. A casing of frozen earth is impervious to rain, and the water quickly runs off to the streams, leaving the earth about the roots of the trees dry all winter long. As the moisture evaporates from the leaves it cannot be supplied by the roots as it can when the ground is damp, and it is probable that many trees will therefore perish.

The American Consul-General at St. Petersburg, writing in the *North American Review* for November, says that at the Chicago Fair the Russian Ministry of Public Domains will exhibit a complete collection of the agricultural products of Russia, including all sorts of fruit, vegetables, cereals, wood, and the products of the stone and metal mills, as well as of the fisheries belonging to the Government. It is intended to make the agricultural branch of the Russian section as complete as possible, that planters and dealers in agricultural products and implements may have an opportunity to judge from personal observation of the state of Russian farming, especially as to such articles as are exported by both countries. The Department of Appanage will exhibit wines in great variety, from the immense vineyards of the Emperor, situated in the Caucasus, Crimea and Bessarabia.

The stress which is laid in France upon the proper placing of outdoor monuments is shown by the fact that before the monument to the painter Millet, recently unveiled at Cherbourg, was begun the site for it was carefully selected by Chapu, the sculptor charged with its making, aided by Bonnat, the famous painter. The selected spot is at the end of the public garden, in front of a group of ancient trees which cover it as with a dome of verdure, and the monument was evidently designed to fit such a site, as reproductions of it show that it is intended to be viewed only from the front and sides. It consists of a tall granite pedestal adorned with branches of Oak, which rise so as to form a sort of background for the base of the white marble portrait-bust which stands on the pedestal; and at the base of this last stands a peasant-woman's figure, recalling those which Millet so often painted, holding up a child, who lays a Palm-branch at the foot of the bust.

On the plains of Auvergne, the altitude of which is 300 metres, and in almost all the elevated parts of southern France and well into the Pyrenees, may be found a large species of the Composite family, *Carlina acanthifolia*, a hardy and very ornamental plant with pinnatifid leaves, a little hairy on the under surface, and bordered with spiny teeth, and with violet-purple flowers which are disposed in a single head. Possessing no stem, the plant lies prone on the ground, with its leaves outspread, resembles a great Artichoke, and, according to a writer in the *Bulletin d'Arboriculture et Floriculture*, of Ghent, it might be utilized for food. Indeed, Monsieur Clos, Director of the Jardin des Plantes at Toulouse, reports, on the authority of Dalechamp, that in the sixteenth century a considerable use was made of it in the province of Dauphiné, where

it was considered superior to the artichoke. It was also valued for the table in the Pyrenees and the Lozère, where a hill-side near Mende was rented for 300 francs a year for its cultivation.

All persons interested in botanical science will be glad to learn that the herbarium of Wm. M. Canby, of Wilmington, Delaware, has been secured by the New York College of Pharmacy, and it will, therefore, be in good hands and will be kept together. The \$6,000 which was paid for it, according to published statements, will hardly cover the actual money which has been expended upon it, to say nothing of the intelligent work which Mr. Canby has given to it during thirty-four years in traveling, collecting, corresponding and arranging. The number of species in this collection is not less than 26,000, and it may reach 30,000. The number of specimens to illustrate these species amount to 150,000. Every specimen is properly mounted and arranged in genus covers. The herbarium has already aided the studies of almost every American systematist of consequence, and specimens have often been sent to European botanists for their inspection. It has, therefore, not only already been of extended use, but has had the benefit of supervision by many eminent men.

A correspondent of the *Levant Herald* writes that a formidable danger threatens the Valonia Oaks of Asiatic Turkey in the shape of swarming caterpillars, which eat off the leaves early in the spring, and therefore destroy the fruit. For many years this pest was confined to small and isolated groves, but during the last four years it has extended its ravages until it prevails among all the Valonia-groves of the plain of Scamander and neighboring localities. The injury done to the trees is serious, and the yield of acorns is reduced in quantity and shrunken in size. A few more summers of such an infliction will bring absolute death to the forests. No organized measures for the extermination of this insect have been set on foot, and energetic proprietors who attempt to rid their trees in autumn of the eggs laid by the butterflies are handicapped by the imbecile apathy of their neighbors, who consider it impious to resist what they call a visitation of Providence, and will not stir a finger to help themselves against the pest. Of course, caterpillars which breed on these infested trees spread to the trees of the man who has been at the trouble and expense of clearing away the insects, and defoliate them also. Unless the evil is not eradicated it will seriously diminish one of the staple products of Turkish soil, and the danger is sufficiently alarming to call forth state intervention. If every proprietor were compelled under penalty of a fine to cleanse his trees by the middle of December, a work which does not seem to be very difficult, the pest might be overcome. The acorn-cups of this Oak, *Quercus ægilops*, contain much tannin, and thousands of tons are annually exported from Smyrna and other ports to be used for tanning, dyeing and making ink.

In an interesting article, called "Waste Products Made Useful," published in the *North American Review* for November, Lord Playfair says: "As to perfumes, there are some which are really oils, and others extracted from flowers. There are others which are made artificially, and curiously, most frequently, out of bad-smelling compounds. The fusel-oil, separated out in the distillation of spirits, has a peculiarly nasty and sickening odor. It is used, after treatment with acids and oxidizing agents, to make the oil of apples and the oil of pears. Oil of grapes and oil of cognac are little more than fusel-oil largely diluted. Oil of pineapples, on the other hand, is best made by the action of putrid cheese on sugar, or by distilling rancid butter with alcohol and oil of vitriol. This oil is largely used for making pineapple ale. Many a fair forehead used to be damped with 'Eau de Millefleurs' without knowing that its essential ingredient was got from the drainings of cow-houses, though now it can be obtained cheaper from one of the constituents of gas-tar. Out of the latter is also got oil of bitter almonds, so largely used to perfume soap and confectionery. . . . Perhaps the most important use of gas-tar is in the manufacture of alizarin, the coloring matter found in the root of the Madder-plant, so extensively used at one time in Turkey-reds and in calico printing. The discovery of its artificial preparation from the waste products of tar has destroyed a great agricultural industry which flourished in Turkey, Holland, Alsace and other countries. . . . By a very interesting series of transformations one of the constituents of coal-tar has been changed into the coloring matter of indigo. Hitherto the cost of production of artificial indigo has been too great to allow it to take the place of natural indigo, the cultivation of which is one of the staple industries of the East Indies. But its cultivators tremble lest they should find themselves in the position of the growers of Madder by a cheap artificial production of indigo-blue from coal-tar."

Landscape-art as a Profession.

FEW weeks pass in which we do not receive a letter or two inquiring what inducements are offered by the profession of landscape-gardening to a young man who is looking for an agreeable and fairly remunerative calling. The inquirer usually seems to have an idea that this is an art in which one can readily become a master—indeed, that it is an art in which any one who is endowed with what he considers a “love for nature” is already well equipped. Of course, these people have a confused idea of what they mean by landscape-gardening, which may stand for one of the highest of the arts of design, or it may mean something which is purely handicraft. One of the leading daily journals in New England, for example, not long ago spoke of the planting of some Petunias and Geraniums about the pedestal of a statue in Boston as a specimen of landscape-art. Last week we tried to show that an artist was needed whose true province was to comprehend the work of the architect and the gardener and to arrange the building and its surroundings so as to form a landscape with unity of design. Successful work in this field certainly demands taste and training of the highest kind. There may be gardeners who are artists in their line, and architects, too, who are artists, but, after all, there is a necessity to cultivate the conception of landscape as composed of the harmonized works of these two kinds of artists. Whoever harmonizes them successfully, whether he calls himself a landscape-architect or not, is an artist of the first rank.

We can say, however, to all inquirers that there is little demand now for specialists in this field, for few people have yet realized its possibilities. It is true that there is a dawning conception of the truth in this matter, and the Columbian Fair grounds will, no doubt, prove an influence of surpassing importance in showing how an artist, working with and through architects, could make possible such a creation as the White City. When a few more men like Mr. Olmsted, who is neither an architect nor a gardener,

technically, shall have proved to architects and to gardeners, as well as to the people generally, the supreme importance of general design in the arrangement of buildings and grounds, there will arise a call for designers in this field. In very few of the professions are there many persons who excel in design, and, perhaps, there are not more than half a dozen men in the world who have achieved greatness in this field of landscape-art. To be eminent, much study must be added to original natural ability, for the artist must have enough knowledge of the principles of engineering and architecture and gardening to know their possibilities and to work through experts in them. And yet it is probable that as the call arises this profession will be crowded as full as any of the others. Most of these practitioners will, probably, do very indifferent work, but then there are not a few sculptors and landscape-painters and architects who do indifferent work, too.

This somewhat exalted and yet, as we believe, fundamentally true conception of the functions of the landscape-architect ought not to weaken the purpose of any one who is preparing to enter the field of what is often called landscape-gardening. If the day should ever come when designers such as we have described will always be employed in works of importance, there would still be as much need of an artistic gardener as an architect. Such a man would always be needed to carry out the details of any great design and realize its suggested features, and even now it is probable that a man who is possessed of a good knowledge of plants and some artistic training—the more he has the better—might be able in almost any suburban neighborhood to work up a practice in various subordinate branches of garden design and render good service to owners of small places. The call for such work is proved by the fact that planters are constantly asking for advice and suggestions, as every nurseryman knows, when he receives an order for plants. The ideal landscape-gardener, however, is free from such business connections. The reason of this is that the relation of the landscape-gardener to his client should be strictly professional; that is, he places his talent and training and experience entirely at the services of his client, and owes no business obligations to others. This does not mean that it is improper to take commissions for selling trees, still less does it mean that a nurseryman's agent may not have good ideas about planting, but the only way in which the professions can win complete confidence is to have no commercial connections.

It seems, therefore, that a young man of fair intelligence who is known to accept no commissions and buys his material in the cheapest market might soon gain a position with an assured, if not a large, income. Several of our agricultural colleges are giving instruction in the elements of garden-art, and furnishing their pupils with something beyond a knowledge of how to graft and propagate and do the other routine work of gardening. Besides this, there is a limited number of men in various parts of the country who are already doing creditable work in this field, and good schooling can be obtained by study and practice under their direction. In this way a class of men can be trained who, while not landscape-architects in the broad sense of the term, may yet do much to redeem country and suburban places from the commonplace look too many of them now wear.

A Museum Specimen of Sequoia gigantea.

A SECTION of a trunk of one of the California Big Trees is now almost ready to be set up in the Jesup collection of American woods in the Museum of Natural History in this city. Like the other specimens of this collection, this one is four and a half feet in long, measuring with the grain, but it is rather more than twenty feet in diameter, and when fully prepared the great wheel will be set up on its rim as the beautiful specimen of Redwood is near by. The tree grew on land now owned by the King's River Lumber Company, near Sequoia, Fresno County, California, a long

day's ride up the mountain from Visalia. To make transportation possible it was split into twelve sections, the centre-piece being round, and eleven others radiating from it. It is an admirable specimen, with perfect grain and apparently no wind-checks, although through one of the sections there is a narrow decayed tunnel something like eighteen inches long and an inch or two in width. Outside of this, however, the trunk is perfectly solid, and this decay probably came from some injury to the trunk, which may have been bruised by a falling tree; and if we can estimate time by annual rings of growth the accident happened at about the date when the Pilgrims landed at Plymouth. Mr. S. D. Dill, who has prepared all the specimens for this great exhibition, is now riveting the segments of the giant trunk together with great iron bolts, so that it will be perfectly solid when it is finally ready for its position in the centre of the collection.

The tree from which this trunk section was cut was one of a few trees left standing of a once magnificent Sequoia-grove, and the stumps about it show that their growth was very large, one not far from this tree being forty feet in diameter. The remains of the old mill which has turned these venerable trees into lumber is still there, but other mills are at work cutting from 125,000 to 130,000 feet every day. It may be said that the Converse Basin tract of Sequoias, which belongs to the King's River Lumber Company, is about ten miles back from the place where this tree was cut, and Mr. Moore, the Superintendent of the company, estimates that there is enough of that one kind of timber on the tract to keep these mills running at their present capacity for fifty years. When the trees which stand high up on the slopes of cañons are felled the logs are cut off into proper lengths. They are then blown apart by dynamite into halves, quarters and eighths, and a powerful steam-engine, with a steel cable, draws this split timber down to a greased tramway of round peeled logs, over which they are shot away to the mill, near the mouth of the cañon. They are then sawed up into lumber of proper sizes and floated down through a V-shaped flume from the mill to the railroad, sixty-two miles away. This flume is supplied by a large reservoir in the mountains. Although when dry the Sequoia is one of the lightest of American woods, it is very heavy when full of sap, and will not float readily until it is seasoned, so that the timber needs to lie some time before it is floated out of the mountain. The lumber looks very much like redwood, and is sold under this name. Indeed, it is only distinguished from redwood by the eye of an expert.

This particular tree was called "Mark Twain," and girthed sixty-two feet at eight feet from the ground and ninety feet at the surface. It was a straight, handsome tree some three hundred feet high, and without a limb for about two hundred feet from the ground. Mr. Moore estimated that it contained four hundred thousand feet of lumber, and the specimen cut, four and a half feet long, weighed over thirty tons. It took two men about three weeks to cut it down. The axemen chopped out deep notches on the opposite sides of the tree, leaving a comparatively narrow strip through the centre untouched. A notch was then cut at one end of this centre-piece on the side toward which the tree was to fall, as seen in the illustration (page 546). Two long cross-cut saws were then welded together and the workmen began to saw in horizontally opposite the cut last mentioned, and wedges were driven in until the tree toppled over. It was while the tree was in the act of falling that the photograph from which this illustration was taken was made by Mr. C. C. Curtiss. The other illustration (see p. 547) gives some idea of the size of the tree at the ground. Fifty men of the Lumber Company's force are here seen standing out on the sap-wood and bark of the stump, and the tools with which the giant was overthrown lie in the centre, where there is easily room for a hundred more men. Of course, the butt of the log that fell was sawn off above the bevel made by the axes, and in a plane perpendicular to the axis of the log,

so that the bottom of the specimen in the museum represents a cut about ten feet from the ground. A section of the log next above this has been secured as a specimen for the British Museum.

Every lover of nature must be rejoiced at the fact that the National Government has taken possession of several of the most extensive groves of Big Trees that remain in California, so that they cannot pass into private hands and be turned into lumber, a fate which has already befallen so many of these oldest and noblest inhabitants of our mountain forests.

Public Forests and Public Parks.

DR. EDWARD EVERETT HALE has an interesting article in the November *Cosmopolitan* on Epping Forest, which was restored to the public in the year 1882, after a long and stubborn contest, the corporation of the city of London conducting the fight in behalf of the people. The forest once covered an enormous territory, and at the time of the Long Parliament its area was still sixty thousand acres. This had been steadily encroached upon, and when the contest for its restoration began in 1871 the greater portion of it had been appropriated to private uses. When it was finally restored its area amounted to nearly nine square miles, or something over five thousand acres, still a magnificent domain, of about the same length, and somewhat larger, than the territory which it is proposed to convert into a public open space at the Blue Hills of Massachusetts, near Boston. The Blue Hills, however, or the Massachusetts Forest, as perhaps it may appropriately be called, since these hills gave the state its name, are very different in character from the Epping Forest, and, being of a mountainous nature, would be a grander possession for the people of Boston than Epping is for London.

Epping Forest had its origin as a public domain in the fact of its being common land. Many commons still exist in England as survivals of a primitive communal system—an institution that was transferred to New England by the early settlers, whereabouts the only traces now left are to be found in the local commons of various old cities and towns, that of Boston being the most prominent. Dr. Hale remembers, for instance, when cows were pastured and carpets were beaten on Boston Common, and although these practices were later forbidden by city ordinances, he thinks that very likely, if tested in the courts, those rights would be found yet to exist. The right of commonage in England still carries with it a great many privileges for the communities possessing it, and in the case of Epping Forest its exercise interferes considerably with the uses of the place for public recreation. The inhabitants of the neighboring villages are the commoners, and they pasture their cows, oxen and horses there, a practice which interferes with the undergrowth and the lower growth of trees. Goats and sheep, however, are said to be "non-commonable."

Another right of the commoners, that of "lopping," enables them to lop for fuel in fagots any branch not bigger than a man's finger. As firewood is valuable in that part of the world, this privilege was availed of to its utmost extent, greatly to the damage of the trees; therefore, under the new régime, the villages have been persuaded to surrender this right for certain other privileges and the sum of £7,000. Considerable damage is still done by forest-fires, set either carelessly or wantonly.

The forest is the favorite place of recreation for the people of London, and the railways carry excursionists thither at fares of a shilling for the round trip to and from the various stations, with half-fares for children. Sunday is a favorite day for excursions, and men go from London very largely in clubs, making special arrangements for picnic places, which are reserved for them. In making its application, each club has to be represented by some one who is responsible for the observance of the park regulations. The maintenance of order is entrusted to a chief and thirteen keepers. In winter and spring one hundred additional men are engaged as a sort of foresters, while in summer only fifty, or thereabout, are needed. The keepers have comfortable houses provided for them, free of rent, in various parts of the forest, and are allowed, besides, twenty-five shillings a week, while the other men are paid twenty shillings a week.

The roads are kept in order by the regular highway authorities. Of the roads Dr. Hale says that they are never finished with the "absurd detail which so often deforms American parks," but in good enough order for any practical purpose. "There is, however, no fiddle-faddle weeding of the edges or cutting out of occasional brambles, such as our park-makers fancy."

And again he says of these roads, "There is none of that dandy-Jack nonsense which weeds up by hand Rue and Mint and Cumin, which is the pharasaic passion of the people who have our great parks in charge. As a consequence, Epping Forest is kept in order at a cost which would sound impossible in Boston or in New York."

From these remarks by Dr. Hale it is to be feared that he does not recognize the distinction between a public park and a public forest. A public park, like Central Park, in New York, or Franklin Park, in Boston, represents for the entire people what the wealthy gentleman's private grounds do for that individual. They furnish pleasant open-air recreation of various kinds for multitudes. The way in which they are used requires the preservation of a high degree of order and neatness, and these are best secured by the most careful planting and maintenance; moreover, as in private grounds, a considerable degree of elegance is both appropriate and desirable. Ragged edges, ill-kept walks, etc., would give an appearance of shabbiness and neglect which could not fail to be reflected in a loss of respect for the place and consequent abuse on the part of the public.

Experience has always proved that it is easier to preserve neatly kept grounds from wanton or careless disfigurement than it is to protect open spaces which are not well maintained.

A public forest, on the other hand, using the word in its stricter sense, although in important respects different from a public park, is a most desirable form of pleasure-ground, and, fortunately, one that is coming into favor on this side of the Atlantic. The Lynn Woods, with its 2,000 acres of forest and lakes, may be compared with Epping Forest, and in the simple form of its development for recreative purposes there is a close resemblance to that of the London pleasure-ground. A public forest, by its nature, does not demand the finish of appearance required for an urban park. Park finish would be as much out of keeping here as an unkempt and shabby treatment would be in a city park. The roads should, of course, be as well constructed as possible. But the more their borders are left to a natural growth the better. The main things demanded are to give the trees the best chance possible to make the most of themselves; then to provide for an agreeable diversity of growth, and to open out from the roads and paths the best points of view and most attractive landscape-passages. The footways need simply to be made comfortably passable by the removal of obstacles that otherwise would cause unnecessary fatigue in their use. With provisions made for rest and refreshment of the public at convenient points here and there, and with proper policing and precautions against fires, little needs to be done in the adaptation of a forest to public uses.

The public forest, therefore, while one of the most delightful and attractive forms of pleasure-ground, is also remarkably economical in maintenance. Possibly, as time goes on, it may even be made to maintain itself from its products in fuel and timber. Both the public forest and the public park form exceedingly desirable, and even essential, features in the equipment of a large city.

Notes of a Summer Journey in Europe.—XVII.

NURSERIES for the propagation of plants are so abundant in certain directions in the vicinity of Paris that a traveler is very likely to wonder what can become of all the young trees and shrubs and other plants with which the fields seem filled for miles along the lines of travel. Large sections are given up to the raising of seeds, while it takes no small area to furnish all the fruits, vegetables and flowers consumed in the great city. Railroads, of course, bring much produce from a distance, but the largest and best portion of it is raised within a comparatively short early-morning drive from the point where it is to be marketed. The French are a horticultural people, and although pépinières, or propagating establishments, appear so numerous, they all seem to find a good and profitable patronage.

Of course, establishments of this kind vary as much here in the manner in which they are conducted and in reliability as in our own country. It is often interesting to note the specialties of particular dealers, for specializing has come largely into this business as into every other branch of trade, and there are now many firms which do a very large business in a quite limited variety of stock. Unfortunately, there was no time or opportunity for me to visit the famous seed, flower and testing grounds of the Messrs. Vilmorin at Verrieres and other places, but, on the recommendation of Monsieur Ed. André, I had the pleasure of inspecting the nurseries of Monsieur Croux at Sceaux, probably the largest and most interesting of

the suburban nurseries of Paris which are devoted to the business of raising trees for shade, ornamental and fruit purposes. The establishment is situated in a charming little valley in the midst of a beautiful undulating and highly cultivated country, and surrounded by other concerns practicing the same business. In the nurseries of Monsieur Croux a considerable proportion of the trees are grown until they are quite large, so as to meet the demand for specimens for city planting, which will make a show or give some shade at once. The nearness to the city and easy transportation renders this possible, and the trees commonly sold are each large enough to make a good load for a team.

The artificial training of fruit-trees is here carried on to a surprising extent. Probably in no other country are Pear and other fruit-trees so often trained to peculiar shapes, and there are in this nursery great numbers with forms varying from different degrees of espalier, which are most largely grown, to vase-formed, pyramidal, weeping, spiral and other artificial shapes. Of course, the standard, or normal, forms are very largely grown, but a foreigner is surprised at the proportion that are trained to peculiar shapes and at the care taken to get them perfectly symmetrical.

The collection of shade and ornamental trees and shrubs is a rich one and in admirable order, the soil being good and the climate congenial to healthy growth. The winter of 1890-1891 was unusually severe, said to have been the coldest in twenty years, the thermometer registering as low as eighteen degrees below zero of Raumur, with no snow to protect the ground. In consequence, handsome sturdy plants of evergreen Magnolia were very much injured, while even the common Ivy was badly frozen, especially young plants which trailed on the ground. The handsome *Andromeda Japonica* is grown here in quantities and frequently has its flower-buds blighted in winter, as it does in the much colder climate of Boston. Our *Rhododendron maximum* is much used as a stock, instead of the more generally employed *R. ponticum*, upon which to graft other varieties of *Rhododendrons*, as it is considered superior.

It is said that this section of the vicinity of Paris did not suffer so greatly as did some other suburbs from the shells of the Germans during the siege; but the extensive nurseries were ruined by the encampments of the enemy, and stories are told of greenhouses full of Orchids and other rare plants of great value, which, being abandoned, withered and died amidst the scene of desolation. But there were trees which came through these trying times without permanent injury, and Cedars of Lebanon, with trunks over four feet in diameter, are examples of them. Some good-sized trees of the rare *Cedrela Sinensis* are growing here. Although the regular blossoming period is said to be June, one of these trees was, at the time of my visit, in early September, bearing many long, loose, somewhat pendulous panicles of small white flowers. This *Cedrela* seems to be almost unknown to European and American cultivators, except in the vicinity of Paris, where it was introduced from Japan through Monsieur Eugene Simon, and in a few other localities. The tree has very much of the aspect of an *Ailantus*, and, indeed, after its introduction into cultivation at Paris it was described by Monsieur Carrière as *Ailantus flavescens*. But when it flowered in 1875 it was determined from the blossoms that it belonged to the genus *Cedrella* of another family, and that the species had already been described in a flora of China. Although the *Cedrela* has flowered for a number of years about Paris, it has not borne the fruit which would furnish the most striking character in distinguishing it from the common *Ailantus glandulosa*, or "Tree of Heaven." There is, apparently, still some confusion about it, for we find English authorities calling it *A. flavescens*. Its leaves closely resemble those of the common *Ailantus*, but they are usually not so large, the leaflets not so numerous, and they are without the peculiar little lobes on the margins near the base which characterize the leaflets of the "Tree of Heaven." When bruised they do not give out the disagreeable fetid odor of the latter. The flowers are said to have an agreeable fragrance. The wood is rather brittle, and the bark of the trunk is dark gray and rough, exfoliating in strips of considerable size. It is some years since this tree was first tried at the Arnold Arboretum, but it has not yet shown sufficient hardiness to withstand our winters without receiving serious injury. It appears to be little hardier than *Paulownia*, but, no doubt, in some sheltered and favorable situations in a climate as severe as that at Boston it will survive to become a tree. As botanists have collected specimens near Peking and other northern parts of China there is reason to believe that a hardier race may yet be procured than that already introduced. It is said that this tree is commonly cultivated for ornament in China, and that

in spring the young shoots and leaves are used as a vegetable for food.

High cultivation here, as in so many other parts of the world, seems to favor the increase of certain pests to vegetation. Large snails are here sometimes much more destructive to foliage than ever comes within the experience of New England horticulturists, and roots of Pear and other young trees are often badly eaten by white grubs. Mildews, too, revel in this rich vegetation, especially on Roses and Vines. To combat these the same formula is used which is employed in the vineyards of many other parts of France. It is composed of two kilogrammes of sulphate of copper and two kilogrammes of lime in 100 litres of water, and is applied in a fine spray. Without the addition of the lime the leaves are considered liable to injury by the copper sulphate.

A short visit to the principal nurseries of Messrs. Transon at Orleans introduced me to a collection very different in appearance from that at Sceaux, although largely composed of similar material. Trees and shrubs are grown here in very great quantities, and largely sold when quite small, a considerable portion of the stock being shipped to distant places or out of the country. Instead of large specially trained specimens, we find here good-sized areas given up to a single species or variety, the plants often not too large to be shipped by mail if necessary. As an example I may mention that I found thousands of *Spiræa Thunbergii*, which were propagated by green cuttings, this mode of propagation being very much resorted to in this establishment for a great variety of plants. The cuttings are planted almost as thickly together as they can stand in circular patches nearly a foot and a half across in beds of well-prepared sandy soil in the open ground. They are given one good watering and then covered with large bell-glasses or "cloches," which are in turn shaded from the direct sunlight by light mattings of straw. The one watering suffices, and the cuttings require no further moisture until the roots start, which may be in a week or two or a month or two, according to the kind of cuttings. The bell-glasses do away with the use of frames, so much employed in our own country, and they have several obvious advantages over them. They are made of thick strong glass, are about a foot deep and a foot and a half across at the mouth, giving room for a very large number of cuttings when closely planted together. They cost less than twenty cents each. When the cuttings have formed sufficient roots they are transplanted thickly together in rows in the nursery.

The firm has several branch nurseries in localities most suitable to the growth of particular classes of plants, but lack of time made it impossible to visit any of these. The general topography of the country is not attractive, being almost a plain, and the day spent here was the hottest experienced in Europe.

Arnold Arboretum.

J. G. Jack.

Notes from West Virginia.

ON my study-table this morning is a strange bouquet. It consists of white Chrysanthemums, true November blossoms, and a large spray of purple Persian Lilac, filling the room with fragrant memories of May. Our beautiful Persian Lilac-tree—for the shrub, fifteen feet in height and twenty in spread of branches, may well be called a tree—has been forced into bloom by the warm sunny days of the past month. Down in the shrubberies a Red Bud is blooming almost as lavishly as it bloomed in April. Such a blending of the flowers of spring with those of November is a strange sight, and befits this most singular of seasons. The fifth month of drought has now begun, and all the world hereabout is turning to dust.

Indoors we find some comfort in the large room given up to plants, where we can control the water-supply. Long experience in window-gardening has taught us that it is wise to have a background of beautiful foliage-plants for the few flowers that can be coaxed into bloom in the dark winter months. Some Palms and Ferns are a necessity, and there are some desirable plants which are charming both in and out of bloom. One of these, not often seen in windows, is *Imatophyllum miniatum*, which seems perfectly at home in an ordinary sitting-room heated by a base-burner. Our specimen grew finely in a shaded position on the piazza throughout the summer, and is now about to bloom. It has long sword-shaped dark green leaves of good substance, curving out gracefully on all sides. It requires a constant supply of water at the blooming period. It is of the easiest culture, does not seem to have any insect enemies, and is one of the most graceful and ornamental of plants. The ideal window-garden should be liberally supplied with fragrant plants. A little pot of Thyme is a constant joy, and a place should be found for a few sweet-scented

Geraniums, such as the Rose, Nutmeg, Apple and Lemon scented varieties. Heliotropes are capricious plants, often refusing to live under the most careful treatment. They need plenty of water, heat and sunshine. *Olea fragrans* blooms a long time, and, with care, makes a fine window-plant, filling the room with its delightful perfume. It needs sun, and the leaves should be frequently sprinkled, but too much watering of the roots will cause it to drop its foliage.

The plant-room should never be overheated. We endeavor to counteract the drying effect of our base-burner by frequent sprinkling of our plants, giving air in mild weather and by resting the pots on trays filled with moss.

This is the Chrysanthemum month, and we rely upon these flowers to put the finishing touches of beauty to the window-garden. Next month will be the turn of Roman Hyacinths, Freesias and of Jessamine and *Daphne odora*, which is now full of promise of bloom. Large smooth-leaved Begonias, that are almost always covered with scarlet blossoms, are very useful to lend a touch of gay color here and there, and some of the rough-leaved varieties, such as *Gloire de Sceaux*, are always beautiful. This has bright leaves of red-bronze, and should be placed where the sunlight can filter through the foliage. A striking defect in many window-gardens is the commingling of discordant shades of crimson and scarlet. This may be easily obviated by arranging all the light and dark scarletty reds in one window and the deep crimsons and crimson-pinks in another, with some white flowers in each.

For the past week the atmosphere has been dimmed by a dense cloud of smoke, through which the rays of the sun can barely struggle, while at night the moon gleams faintly with a strange red light. The smoke comes from the mountain fires, which have been burning in every direction north, south, east and west of us. The mountains themselves are obscured in the day-time, but gleam at twilight with an ominous glare that tells of the destruction of untold acres of timber. The aspect of the country is barren and desolate, parched to winter deadness. The rivers are so low that they have an unfamiliar appearance; even the Potomac has dwindled almost beyond recognition. The old people tell us that there has not been such a drought for forty years. Yet a good rain may yet save much of the wheat-crop.

Danske Dandridge.

Plant Notes.

Dendrobium formosum giganteum.

THIS *Dendrobium* has long been known both to science and cultivators as the finest of that section of the genus to which it belongs—namely, the *Nigrohirsute*, or those whose stems are clothed with short dark hairs, as in *D. Jamesianum* and *D. infundibulum*. Although *D. formosum* has been known to gardens for over fifty years, its cultivation in Europe does not seem hitherto to have been very successful. It is widely distributed through India and Burmah, and is never found at any great altitude, but usually on the plains, where high temperatures are the rule both in winter and summer, with rain in some districts eleven months in the year. From these few facts, made known by those who had seen the plants growing, it has been hitherto thought necessary to grow *D. formosum* in the hottest house the year round, and we may add that it is fortunate that the plant is plentiful in India, otherwise we should not be able to procure it at such a low rate as we can at present. All plants need a season of rest, and, even though they come from the hottest regions of the globe, nature has provided for this period of rest in various ways. In Veitch's *Manual* we are told that "the plants are sometimes exposed to a temperature of 110 degrees, Fahrenheit, in the shade, when the stems are much reduced in size by the heat." During the growing season we keep the plants suspended in the house where *Calanthes* are grown, which is now kept at seventy degrees at night, and our plants have done remarkably well this season; the old bulbs made in their native woods are in some cases surpassed in size by those made this year, and they are now commencing to flower freely. After the flowering season the plants will be wintered in a temperature of fifty degrees at night in a cooler house, until signs of growth are apparent next March or April, when all the heat and moisture available will be given and maintained

until the flowering season is passed. Under this treatment Mr. George MacWilliam, of Whitinsville, Massachusetts, has grown and exhibited in Boston, perhaps, the finest *D. formosum* ever seen in cultivation, and this fact appears to be due to the long rest given in the cooler temperature. *D. formosum* is an exceedingly ornamental plant when in bloom, as the foliage of the past and present year is often retained on the plants as a set-off to the large pure white flowers, which are sometimes four inches in diameter, the lip having a conspicuous yellow blotch, varying in some plants from bright orange to pale lemon-yellow. The flowers are very durable, lasting several weeks in perfection. As the plants seem to grow best when suspended from the roof of the house, basket-culture or perforated pans seems the best treatment for them, as the roots like to ramble, and seem to resent confinement in pots. I have seen it stated that wood-lice do not feed on living roots of Orchids, being content to live on decayed portions, but I am satisfied that they are very partial to the roots of this *Dendrobium*, and for this reason the plants are often plunged in water a few minutes to drive out the wood-lice, when they are easily caught. It should be stated that this species flowers with the completion of growth, hence the rest is given after the flowering period, while in the majority of *Dendrobiums* the resting season precedes the flowering time. The statement of some eminent authorities that horticulture is necessarily an empirical art, seems to be supported by the fact that it takes a temperature of 110 degrees to rest this plant in Burmah, while we can accomplish the same result by reducing the temperature twenty degrees from normal, while we could not imitate the conditions noted under which the plant grew at home.

South Lancaster, Mass.

O.

Foreign Correspondence.

London Letter.

PHALÆNOPSIS CULTURE.—I recently visited the garden of Mr. Wigan at East Sheen, near Richmond Park, a garden famous for some classes of Orchids, and particularly for *Phalænopsis*, which are grown exceptionally well there. Mr. Young, the grower, kindly furnished me with some details of the treatment he finds most suitable for these plants, and these may be useful to others. The *Phalænopsis*-house at East Sheen is twenty-five feet by fourteen feet, with a low-span roof, and it stands on the north side of a high wall, so high as to completely shade the house from sunshine all winter. The house has bottom ventilators only, water-tanks below the stages, which are planted with *Fittonias* and similar low-growing foliage-plants. The paths are formed of gravel, which Mr. Young believes in keeping forked quite loose. The *Phalænopsis* are all suspended from the roof. They are planted in teak baskets, small in comparison with the size of the plants, and they are partly filled with potsherds, partly with sphagnum. Mr. Young does not use any charcoal, and he uses sufficient sphagnum only to hold the moisture about the roots of the plants in hot weather. They are all carefully replanted in May, when they are allowed to get dry, and then all the old moss is washed out with the aid of a syringe and replaced with new. The plants are not transferred to larger or new baskets unless it is quite necessary. During summer they are kept moist, almost saturated at the roots, and in hot weather the foliage is slightly dewed over with the syringe. The atmosphere is kept at saturation point, and the temperature at from seventy to eighty-five degrees. In winter less water is given; only when the moss about the plants is dry are they watered. Mr. Young dips the plants overhead in a bucket of water to water them. In winter the temperature is allowed to fall to sixty degrees at night and sixty-five degrees by day, except when the weather is mild, when the temperature is kept about five degrees higher. There are about 300 plants of *Phalænopsis* in this house, some of them being very fine

specimens with leaves a foot long. Almost every one of the best of the species and hybrids is represented, while of such kinds as *P. Schilleriana*, *P. grandiflora* and *P. Stuartiana* there are many fine plants. The effect produced by these *Phalænopsis* when in flower in January is a most beautiful one. To grow them well one requires much patience and proper conveniences, which are not of the most inexpensive kind; I think I must add also the element of luck as having something to do with success. But when they do behave themselves *Phalænopsis* fully repay all the trouble taken with them. A great deal appears to depend upon the position and shape of the house. If one can only find the house that suits *Phalænopsis* their cultivation then presents no exceptional difficulties.

CATTLEYA LABIATA (Warocquena).—This grand Orchid is the glory of the Orchid-house in October. It is the principal attraction one meets with in Orchid collections in England, a gratifying circumstance, seeing how rare and coveted this plant was before it was discovered in such abundance by the great English and Belgian Orchid collectors. It is good-natured under cultivation even for a *Cattleya*, and it appears to flower at least as profusely as the best of them. Where it cost guineas a year or two ago it scarcely costs shillings now. At a London auction sale this week I saw fine healthy plants, with a dozen or more pseudo-bulbs and in most cases bearing several flower-sheaths, sold for from eight to fifteen shillings each. A large box of cut flowers of this Orchid, shown by Messrs. F. Sander & Co., gave buyers an opportunity of seeing the character of the plant. It ought certainly to rank among the twelve best garden Orchids. One meets with so many frauds in the shape of Orchids—I mean in their having good looks coupled with a very bad character in the garden—that it is a genuine pleasure to find one to which too much praise cannot well be given.

CATTLEYA ALEXANDRÆ.—Of this I am a little suspicious, a plant of it having flowered lately at Kew—the first to flower anywhere, I believe. It is one of the *C. guttata* class, and, judged by the plant flowered here, one of the worst of them. The flower is three inches across, like that of *C. guttata*, var. *Leopoldii*, the sepals and petals dull greenish brown with a few reddish blotches, and the labelum rosy mauve. Of course, the Kew plant may be the worst possible variety, and the collector who pictured and described this discovery as a many-flowered beauty may not have seen anything so poor as the first flower that has opened in England. We hope not.

GLADIOLUS OPPOSITIFLORUS.—The re-introduction of this plant, which has lately been sent from the Cape to Kew, where it is now in flower, will, we hope, enable those who are interested in the history of garden *Gladioli* to decide soon a question which has been a puzzle for many years, since Dean Herbert's time, in fact. According to the worthy Dean, *G. Gandavensis* was raised in 1837 from *G. oppositiflorus* and *G. Natalensis*, and not, as was stated by others, including the raiser himself, one Beddinghaus, a gardener, from the last-named and *G. psittacinus*. According to Herbert, this latter cross is almost impossible; at any rate, he could not accomplish it, though he tried many times. *G. Gandavensis* was the first of the large-flowered, beautiful, easily cultivated hybrid *Gladioli* that originated in gardens. Monsieur Emile Lemoine, of Nancy, who is an authority on all questions relating to garden *Gladioli*, has recently stated that a French court gardener, named Souchet, set to work to breed *Gladioli*, about forty years ago, by crossing *G. Gandavensis* with *G. blandus*, *G. ramosus* (this, according to Herbert, is itself a hybrid between *G. oppositiflorus* and *G. cardinalis*), and he was soon followed by other French gardeners, who made of *Gladioli* a specialty. Our Mr. J. Kelway has done as much as any one man toward the improvement of *Gladioli*. He obtained Souchet's hybrids in 1857, and crossed and saved seeds from them. The point I wish to emphasize is this: If Herbert was correct in stating that *G. oppositiflorus* was the parent of two of the most valuable of the original hybrids, viz., *G. Gandavensis* and *G. ramosus*

(of gardens), then in that species we have the principal progenitor of the present magnificent race of *Gandavensis* Gladioli, and through them of the *Lemoinei* and *Nanceianus* races. *G. oppositiflorus* is six feet high and has a spike two feet long of large white flowers with amethyst stripes. At least a dozen flowers are open together, and they are arranged in two straight rows on each side of the spike. The first flower opened a week ago and it is still fresh. It is possible that the lateness of its flowering at Kew is due to the corms not arriving here till June. Should, however, the plant really flower regularly in October and November it might be possible, eventually, to obtain from it a race of Gladioli to bloom at Christmas. The exceptional stature of *G. oppositiflorus* and the chaste

ishment from twelve o'clock till sunset. This arrangement has worked well for fifty years. Now, however, the British public, or, at any rate, that portion of it which lives in the neighborhood of Kew, has decided to ask for access to the gardens for the whole day. It is surprising how many people there are who look upon Kew as a pleasure-park merely.

Cultural Department.

The Grape Season.

THE remarkable grape season of 1892 opened on my grounds with the ripening of Moore's Early on the 9th of September, just nine days later than the same variety ripened last

Fig. 92.—Felling a *Sequoia gigantea* in Fresno County, California.—See page 541.

beauty of its flowers ought to make it valuable to breeders of Gladioli. The Kew plants have been grown in pots in a cold house. They do not appear to be at all drawn.

EARLIER OPENING OF KEW.—An agitation has been started to get the gardens at Kew opened to the public in the morning as well as in the afternoon. At present the use of the gardens before noon is limited to professional people and others specially interested, such as painters, photographers, etc. These are admitted by ticket, about a thousand people annually availing themselves of this privilege. In the morning, too, all the rough and dirty work, watering and syringing indoors, are got through, so that by noon the whole place is in trim and ready for the crowds of people who then have the free run of the whole estab-

year, and there has not been a rainy day since which has interfered with harvesting the crop. This unprecedented state of things enabled the grapes to ripen thoroughly and to attain their best quality, so that there was less loss from splitting than I have ever experienced. The Pocklington suffered most from this, which proves this variety to be chronically weak in any season here, and on my soil its redeeming qualities do not suffice to warrant its retention; and yet I occasionally meet a man who relishes its pronounced foxy odor and tough pulp. On the other hand, Woodruff's Red, which has always cracked badly heretofore, has showed scarcely any tendency to do so this season. The clusters were large, generally shouldered and compact, and the grapes ripened up to a bright brick-red, which made them very attractive to the eye. The quality, to my taste, though never very good, was rather better than usual, but customers say they "look delicious," and perhaps

they sell better than if they tasted delicious and were less attractive to the eye.

Brighton and Lindley are my favorite red Grapes, and both succeeded remarkably this season. Both are liable to fail in setting sometimes, but this defect has not been noticeable this year. These grapes were near perfection, and I am glad to be able to detect a growing appreciation for fruit of such excellent quality. The late Lowell Mason once had some Brighton grapes for dessert, and when inquiring where they came from he was surprised to find that they were grown in his own garden from vines which I had sent him. On verifying the word of his gardener, he said, with emphasis, "Well, if we can grow such grapes out-of-doors, there is no need of bothering with hot-house varieties." Brighton is early and sometimes loses in quality late in the season. But the Lindley is later and supplies the place of the Brighton when its quality fails.

quality. It would seem as though such a season as this would have secured the best development, but I was not satisfied with it.

Green Mountain promises to be the earliest white Grape, with Colerain a close competitor. Eaton has size and good looks to recommend it, but it lacks that quality of sweetness which makes Worden and Cottage so desirable. However good a grape may be in other respects, if it lacks sugar with its acidity it is a failure. There is the same lack of sweetness in Grein's Golden, Missouri Riessling, Noah and Elvira. Lady Washington is better than ever, and Brilliant would delight the taste of a most exacting amateur. The new white Grape, Esther, fruited here for the first time and proves to be of good size, both in berry and in cluster, and of fair quality, although another season will be required to fully test it. The same may be said of Rockwood, and both appear to be late in ripening.

Fig. 93.—Stump of *Sequoia gigantea*, on land of the King's River Lumber Company.—See page 541

Niagara still holds its own against all competition thus far among the white Grapes for the size of berry-clusters as well as productiveness, while the quality meets with universal commendation when grown as I grow it and fully ripe.

Worden, Cottage, Wilder, Marianna and Herbert hold their own as desirable black kinds. Cottage sometimes drops badly, but this year the fault has not been apparent, showing that there is something in the season to counteract this failing. There is little to choose between Delaware and Berckmans. They are identical in size and color, and equally good in quality. The latter fails in fertilizing sometimes, which may be due to lack of proper company, but both are rather too small to prove profitable for me. Diamond has never reached the ideal which I had formed of it from high commendation in other sections. I am still hoping that another year will give an increase in size of berry and cluster as well as in good

Catawba, Highland and Black Defiance ripened fairly well, which they do not usually do here.

Anthraxnose was the only serious malady which troubled our vines, and there is very little mildew or rot, both of which can be brought under control. The early season came on slowly, and was very wet, which made cultivation difficult and troublesome. Warfare with weeds had to be constantly waged, with the advantage usually on the side of the weeds. The vines, too, felt the same exhilarating influence, and grew abnormally, so as to make pruning a great task. Since July, however, we have had a continuous drought, with only enough water in occasional showers to lay the dust on two or three occasions. Strawberry-plants have not made half their usual growth, and there has been far less fall setting than usual this year.

Montclair, N.

E. Williams.

Lettuce as a Greenhouse Crop.

IN recent numbers of this journal we have reported some experiments relating to greenhouses and greenhouse-work, an account of which was published, with full details, in the September *Bulletin of the Ohio Agricultural Experiment Station*. Mr. W. S. Turner, of the Horticultural Department of that station, has been giving some attention to the growing of Lettuce under glass, and we quote herewith a condensed statement of his experience in this direction :

For germinating Lettuce-seed well-pulverized compost soil is good, although we consider black muck better than anything else we have ever used, as it holds moisture well, is not lumpy, and the plants can be taken from it for transplanting without breaking the small roots, as happens in heavier soil. Use flats for sowing seed and first transplanting. They may be easily moved under benches, or from a warm to cooler, or light to darker location, as the seed or plants may require. This saves space, either in greenhouse, hot-bed or cold frame. Sow seed in drills one and a half or two inches apart, making the drill marks one-fourth of an inch deep, having the soil in flats somewhat packed, so that the marks will be of uniform depth. Cover by sifting with the hand sufficient fine-screened muck or soil over the box to cover the seeds from sight, smoothing over with a stick or board.

Care should be taken in watering to use a finespray, or, better still, to set the flats for two or three hours in the water-bench and irrigate from below. There is considerable danger of the young plants damping off in the dark weather of winter or early spring. To avoid this the flats are kept in as warm, well-ventilated a place as possible and the soil well stirred, using water very sparingly.

We transplant into flats two by two inches apart when the second leaves are well started; this will be about three weeks from sowing. The soil used should be of rich compost, heavier than for seeding, so that the plants may be taken up for the last transplanting with a lump of dirt about the roots. Stir the soil frequently between the rows to prevent damping off as before. They may remain in these flats about three weeks after this transplanting, or longer if kept in a cool place, or be carried out into a hot-bed or cold frame, as the case may be, for hardening off.

The soil in the beds into which the Lettuce is transplanted the second and last time should be a rich compost, or muck may be used with a mulching of fresh, well-pulverized horse-manure. Set the plants six or eight inches apart. Such varieties as Grand Rapids and Simpson do well six by eight, or even six by six inches apart, but head Lettuce requires more room, at least eight by eight inches apart. Cultivate between the rows as before; water often, but not too heavily, until the plants cover the surface of the soil, then water by pouring on in a solid stream between the rows, from hose or watering-can. This is in order to keep the water off the foliage as much as possible. If large-leaved Lettuce-plants are well drenched the water runs down toward the hearts, and it is very slow in drying out, a condition which is favorable for rot and mildew.

To fight the green fly (*Aphis*) use tobacco-dust, which may be had at any cigar factory; one cent per pound is the cost of it in Columbus. Sift it quite plentifully over the young plants soon after the first transplanting. Use again soon after second transplanting, but when the plants get large it will not be sufficient in the greenhouse, but will answer in hot-beds or cold frames. In the house, fumigate by burning the tobacco-dust, as it burns easily, makes more smoke than tobacco-stems, and is not so dangerous. After fumigating the lice will drop on to the soil, when by sifting the tobacco on them they will be quite thoroughly destroyed.

For convenience in note-taking and reference, we have arranged the varieties into five groups. This grouping is not intended as a systematic classification, but varieties of similar habits of growth are simply brought together. The first group embraces those that form quite firm heads. The second and third groups contain the loose-heading sorts; those with plain, or nearly plain, leaves being placed in the former and the curly-leaved in the latter. Those in the fourth group do not form heads, but loose bunches of leaves merely. Those in the fifth group are Cos varieties.

We consider the first and second groups undesirable to grow in this locality, because there is very little demand for them in the market. They are more subject to diseases than open-growing kinds, they require more space, and it takes a longer time for them to come to maturity. This is especially true of the second group. Of the first group, Perfection White, Forcing and Stone Head are the earliest. Tennis Ball is the best of

this class. Landreth's Forcing, Rawson's Hot-house and New Forcing are no improvement over the Tennis Ball, as far as we have been able to discover. New Forcing is very uniform, but not as firm as the Tennis Ball, and has a bronze tinge, which is not desirable.

Those of the second group resemble one another quite closely in growth, but vary in color. They are all quite good yielders, but very slow in forming heads; among them are Deacon, Boston Market, and the like.

Those of the third group are the most desirable for home and garden growing, being very vigorous, heavy yielders, as their weights indicate, also very crisp and tender; but they are too brittle for marketing, and of such form that they cannot be handled as head lettuce, nor as loose bunch-lettuce, and are, therefore, not desirable for market. Blonde Blockhead, Marblehead Mammoth and Sunset cannot be distinguished from one another except by their labels. This variety is the most desirable of the class, with the exception of the Onondaga and All Cream, which are very silky and pliable in texture, easily handled, but are tinged with red like the Prize Head, making them unfit for market, with possible exceptions. All Cream is much more vigorous, and a heavier cropper than the Onondaga. Tilton's White Star is not specially noteworthy. Henderson's New York is too dark in color to be desirable, but is a very strong grower.

Those of the fourth group resemble one another in growth, but are quite different in appearance of leaf and coloring. The Tomhannock is colored like the Prize Head, but does not form a head, and is much like the Grand Rapids in growth. Black Seeded Simpson is the quickest-growing of all varieties, rightly named by Salzer as the earliest (Salzer's Earliest). It is the most desirable kind for late spring growing in cold frame or out-of-doors. Nellis' Perpetual and Curled Simpson are very nearly alike and not particularly valuable. Grand Rapids we consider the best of all varieties for winter and early spring crop, because of its freedom from disease, fine appearance of leaf and bunch, and good handling qualities. Its one fault is that it is a little slow in coming to maturity, but it makes up for that in steady gain in weight after it is large enough to harvest. Many varieties begin to lose in weight as soon as mature, and hence must be cut promptly, but with Grand Rapids this loss is very small, even if left standing for some time. In the east, head lettuce is grown almost exclusively, probably owing largely to the demands of the markets. Grand Rapids lettuce sells as well or better than head lettuce in Columbus and most other Ohio markets, and is much more profitable to the grower, because it can be planted closer, thus giving a larger yield, and, as above stated, it is less liable to disease. It is so much superior for forcing to all other varieties that those who have given it a trial, plant it almost exclusively. No grower in this state need hesitate to plant it; in fact, he can hardly afford to plant any other variety. This may seem to be a strong statement, but the facts so far as observed will bear it out. Chicago Forcing is too tough in texture and too dark green to be desirable. Denver Market is too slow in growth and too liable to disease to be of any value. Boston Fine Curled, Green Fringed and Oak Leaf are only suitable for decoration, and may be raised in limited quantities for the holidays.

The Cos Lettuces are so little known and are of such dark green, dock-like appearance, that they could scarcely be given away in this locality, although the inside leaves are quite brittle and good when well blanched.

In market value the average weight of heads corresponds quite closely with the price. In early winter and late spring, small heads of two-ounce weight bring about twenty cents per dozen in this market; four or six ounce heads about forty cents per dozen, although a much larger quantity can be sold in late spring than in early winter. In late winter and early spring two-ounce plants will bring thirty to forty cents; four and six ounce plants from sixty to eighty cents per dozen. It is, thus, very desirable to have the best and largest crop come off in February and March. There is a moderate demand for lettuce at Thanksgiving-time and also at the holidays, but only a limited amount can be sold. All available space should be devoted to lettuce to come to maturity in February or March.

It takes eleven or twelve weeks to grow the early winter and late spring crop, and thirteen or fourteen weeks to grow the late winter crop, as the young plants grow slower through the dark months of winter. By the use of flats four crops of lettuce may be grown in a season, three in the greenhouse and one in cold frames or hot-beds, but all may be started in the house. The young plants occupy the flats about half the time of their growth, so that the entire space required by a crop is occupied only about six weeks. Three crops may be

grown in the house; the first is only a partial crop on account of the moderate demand, the second is the main crop. The third will be partially crowded out because so many other plants claim room in the house in early spring. The third crop may be grown between Tomato-plants with moderate success, and comes off a little before, or at the same time as, the hot-bed crop. For the last crop the plants may be transplanted into open ground or cold frames and then be earlier than ordinary outdoor lettuce.

The possibilities of production may be estimated as follows: We have grown crops on the middle benches that were harvested the last of February and the first of March that averaged one-half pound per plant; at 6 x 8 inches apart this gives one and one-half pound per square foot. At fifteen cents per pound the product would bring 22½ cents per square foot. A fair estimate for the season would be thirty cents per square foot of greenhouse space for the lettuce crop, and about one-third that amount for hot-bed space. This, it must be remembered, is only for Lettuce; other crops following in both house and hot-bed make the space much more valuable. Outdoor space may be counted at five or six cents per square foot. So it may be seen by summing up all the crops together that a reasonable amount of money may be made in raising lettuce, if one is successful.

The necessary elements of success in lettuce-growing may be summed up as follows:

Keep the plants in flats until ready to set in permanent bed. Use rich compost soil. Use good judgment in watering. Cultivate the crop as much as possible. Keep lower dead leaves well picked off. Watch for and fight the green fly incessantly. Grow Grand Rapids, unless the market demands other varieties.

Potting Soils.

HERE in New England, as in most eastern states, it is highly important that a supply of potting material be laid in under cover for the winter's use, and there is no better time to see that the main supply is sufficient to last until after midsummer next. Rose-growers and others are beginning to appreciate the importance of laying in a stock of loam suited to their purpose, and placing it where it can be thoroughly well frozen during winter. I am puzzled to know which are the worst foes of the gardener and florist—those of fungoid origin or insects and true worms after their kind. Of this animal class I feel sure we should have less to dread if our soils were carefully laid in when convenient, and not stacked up in heaps to exclude frost. If its kindly influence were rather invited and allowed to penetrate every inch of the soil, we should hear less of root-gall and eel-worms on Violets, Roses, Carnations, Cyclamens and other plants. Where it is not possible to freeze soil, and insect foes are prevalent, the other extreme must be adopted, and a system of heating the soil should be adopted. There is nothing new in heating the soil to kill insects in the egg and in other stages of growth. I well remember when a boy seeing my father bake his leaf-mold before he dared to use it for choice plants and Ferns. Our most careful attention should be given that the loam is of a good texture; we can make it as rich as we please afterward. Above all, we should see to it that we are not driven to scrape around to get enough soil together at the last moment for our needs. Here is where the trouble begins, which develops and spreads with such fatal effects later on. While I do not advocate storing soil for any length of time before using—six months is long enough—it is a great gain to have all the vegetable matter thoroughly well decomposed before handling it, for in this way much labor will be saved which would otherwise be needed in future weeding.

It was once considered necessary to the successful growth of the commonest plants, as the Carnation or Auricula, to have a great number of ingredients in the soil and in the most exact proportions. Much of this care in compounding soils has passed away with the old-school gardeners who practiced it. We can grow just as good Azaleas to-day in loam and leaf-mold as were ever grown in peat. Ericas and Boronias also thrive in a like compost if made porous. Good well-decayed leaf-soil is invaluable to the gardener, and great care should be taken when storing the leaves to throw out the sticks or branches, for these encourage fungus-growths. Where Pine-trees are common it is well, also, to avoid mixing in the pine-needles; the resin they contain prevents rapid decay, and is in itself injurious. The use of sand in potting composts is not so generally appreciated as it deserves to be. The value of silica in soils as plant-food is small, though appreciable, when compared with its value in rendering available all other plant-foods contained in the compost. If a soil becomes sour it is at once

poisonous to plant-roots, but given a liberal addition of coarse sand the most adhesive soil may be made fertile by its more perfect aeration. The water will pass through readily, and the air take its place until again replaced by water, and thus a perfect system of sanitation is maintained. The quantity of sand necessary must be determined by the texture of the loam.

Where Orchids are grown Fern-root is an essential for the winter's work. The large tufts of *Osmunda*, common in pastures, produce the best medium known to-day for the successful culture of Epiphytes. The tufts should be grubbed up from above the surface level and stored for winter, when it may be prepared at odd times by separating the rhizomes of the Fern from the fibrous roots. It is well, also, to keep the brown fibre separate from the coarser, because older, black portions which underlie the Ferns as they grow upward. *Osmundas* grow in wet, swampy soil as well as in drier uplands. The fibre is best when obtained from the latter source. This so-called peat is now largely exported to England for Orchid-culture there.

Sphagnum-moss is also an essential in most establishments, and to have it in a condition to start growing freely when used it should be gathered as late in the season as possible and stored where it will freeze. It can then be thawed out, cleaned and used at any time; it is a great mistake to be without it, as it cannot be procured here until April, when a great portion of the work is done for which it is required. Sphagnum needs a rest, like everything else that grows, and, if gathered late, it has already gone to rest and can be stored without injury if moist enough to freeze.

South Lancaster, Mass.

O. O.

Correspondence.

Echoes from Madison Square Garden.

To the Editor of GARDEN AND FOREST:

Sir,—Again a Chrysanthemum season, and, again, the flowers average distinctly larger than the year before. Truly, the cut-flower grower does marvelous things with the plants which he seriously takes in hand. It is only four years ago when the first exhibit of the profession here was made in an exhibition tent in Union Square, and to-day we find the market growers of flowers practically monopolizing the tables and easily winning the rich prizes. It may be questioned, however, whether the flowers are not being rather overdone, and whether there will not soon come a surfeit of such mammoth flowers which have their limitations. In a competition, of course, size counts, and the judges give the prizes to cubic contents every time, questions of taste not being entered on scales of points. Outside the competitions, the specimen blooms collectively, in masses of half-dozens and more, make bold and handsome decorations for large apartments. It is a curious fact, however, that there seems no place for a single bouncing bloom, even with the long stem, which is so potent a charm nowadays. In spite of its mass of color, it does not look well in any vase yet devised, and every one who noticed the numerous specimens carried through the city streets lately must have noted that they always seemed awkward things to manage. A flower which does not compose well with a fair damsel has decided limitations.

How to exhibit large specimen flowers in the least hideous way is a question which is perennially discussed in every horticultural society of the two continents, and there is much to be said on the side of the cup-hunter as well as on that of the committee responsible for making an attractive show for the public, and their views are apt to be somewhat divergent. The sharp cup-hunter favors the boards, because on them the flowers appear to the best possible advantage, as far as the points of competition go. He can dress his blooms and set them up to appear at their very best as the judges come, and there seems no reason why he should not be allowed these advantages. It is no secret that the New York Florists' Club do not favor boards. On their part they have entered into exhibition management with a very high purpose of providing attractive as well as instructive exhibits, and the prizes for cut flowers were mostly offered for those with long stems shown in single vases. The result appeared to me only a modified success, for on the low tables used and under the crowding of the exhibits, one, after all, only saw a glare of confused and sometimes inharmonious colors with no foliage effect. It may be possible to arrange these exhibits more satisfactorily, but the idea seems to me based on two false assumptions. One is that the Chrysanthemum has any foliage worth considering, and the other is that the only desirable stem is one as stiff as a very stiff poker.

The bane of the flower-show is the dilatory exhibitor who

unloads his flowers, in company with numerous others of his kind, just before the judges are ready to act and after the committee has about concluded that there will be nothing to show. There is no possible doubt that with a few hours' study such a competent committee as managed the late show could produce an ideally attractive effect even with the incongruous material, and I have no desire to criticise when there was so much to commend. It might be suggested, however, that the almost primary want of a Chrysanthemum-show is a wealth of foliage-plants to which one could turn one's eyes for rest. Of these we can scarcely have too many, and if the masses of flowers could be broken with them it would seem especially desirable. As no one was ever discovered at a show looking at those floral mops known as plants grown to single blooms, it might be well to drop these from future schedules and devote the money to the encouragement of the growth of plants furnished in a fairly natural way. Such plants have been known to give an impetus to the culture of the Chrysanthemum in gardens, and this seems a point to aim at in a flower-show.

The Chrysanthemum is such a sturdy and lasting flower when grown without heat that it was a pleasure to see the flowers in the Garden this season usually lasting their normal time, in striking contrast to those of last year. The season has been without strong frosts and very dry, and, apparently, no fire-heat had been used by most of the growers, a practice which should be universally followed. A soft, flabby Chrysanthemum is a miserable object, quite out of character, it naturally being one which appears at its best in the open under a clear sky, sparkling in frosty air.

Except in mere size, there does not seem often any material improvement in these flowers. Occasionally there is a new type more or less attractive, but we get no better colors than we have had for some years. Whites and yellows we have always had in abundance of every possible shade, while satisfactory pinks are, as ever, few and far between—none to-day better than Bouquet Fait in color. For grace and refinement, it seems to me that the ordinary grower need not search entirely among the latest productions. Some of the modern kinds, while very useful for the exhibitor, are not desirable for those who grow their flowers to less size, and often under rude conditions or some exposure. These kinds, naturally, have great substance and very numerous petals. Under ordinary culture they are not attractive, and they are specially subject to blight from the first breath of frost.

Every one must regret the absence from the shows of the attractive Pompons and the more fanciful varieties, as the Anemones, which are still enjoyed in many gardens.

Elizabeth, N. J.

J. N. G.

A Rare Plantain.

To the Editor of GARDEN AND FOREST:

Sir,—*Plantago media* was recently found in Framington, Maine. The local botanist who found it, not being able to identify it, sent it to Merritt Fernald, of the Harvard Herbarium, who classified it as above, and stated that so far as known it had only been found in the vicinity of Syracuse, New York. This is, therefore, an addendum to the newly published edition of the "Portland (Maine) Catalogue" of plants, which, of course, does not mention this species in its list of Plantains.

Framington, Maine.

H. P. Keyes.

Exhibitions.

Boston Chrysanthemum Exhibition.

THE growers of Chrysanthemums hereabout may well feel proud of their conspicuous success. The latest products of their skill showed evident progress; and, although the exhibition was not so extensive in some departments as that of last year, the quality of the plants and flowers was distinctly better.

Competition was keenest in the class of specimen plants. Mr. T. D. Hatfield, gardener to Walter Hunnewell, Esq., has of late years been a frequent winner in this field, and he again took the leading prizes. His twelve plants were excellent in every particular, and included specimens of Empress of Japan, Etoile de Lyon, Frank Hatfield, Garnet, G. Daniels, John Laing, Mrs. Bishop, Mrs. Fotler, Tupelo, V. H. Hallock, White Cap and W. H. Lincoln. Mr. Coles, gardener to Arthur Hunnewell, Esq., of Wellesley, was second in the same class with a group of neat, well-furnished specimens, and Mr. Kenneth Finlayson, gardener to Dr. C. G. Weld, of Brookline, third.

The first prize for six plants of Japanese varieties was also

taken by Mr. Hatfield, with Cullingfordi, Ivory, Louis Boehmer, Miss Annie Manda, Mrs. Walter Baker and Walter Hunnewell. The specimen of Louis Boehmer was the finest plant in the hall, and the best ever seen of this particular variety.

Mr. Atkinson, gardener to John L. Gardner, Esq., of Brookline, received first prize for a group of plants arranged for effect, and Mr. William H. Elliott, of Brighton, was second. Nathaniel T. Kidder, Esq., of Milton (Mr. William Martin, gardener); Dr. C. G. Weld and Francis B. Hayes, Esq., of Lexington (Mr. James Comley, gardener), also showed prize-winning groups.

Six admirable examples of superior cultivation were exhibited by Mr. Alexander Montgomery, of the Waban Rose Conservatories, Natick. The varieties were Domination, E. D. Adams, E. G. Hill, Hicks Arnold, Mr. H. Cannell and W. H. Lincoln. These plants were not entered for competition, but they showed a promising departure from the prevalent method of training, the branches being tied to wire hoops, making beautiful broad specimens of semi-globular form. Groups of plants were also furnished by the Bussey Institution, S. C. Lawrence, Esq., of Medford (Mr. Keith, gardener); Mrs. M. S. Walker, of Waltham, and Miss Mary T. Goddard, of Newton.

Mr. Coles secured first prize for a specimen plant of an incurved variety, with Mabel Ward. Mr. Hatfield was first with A. G. Ramsay as a specimen Japanese kind, and a like honor was conferred on Mr. Coles' Savannah, a specimen Pompon. Yellow Ball, a fine plant of which was exhibited by Mr. Hatfield, is a good variety for decorative purposes. The plant was raised by H. A. Gane, of West Newton, and is of very distinct habit and well adapted for specimens, as it is so sturdy that it needs no stakes. It carries handsome flowers of deep orange, and is also excellent for cut flowers.

The greater part of the plants were arranged on the upper floor of Horticultural Hall, and the effect of the grouping could have been materially improved by the introduction of a few Palms, Ferns and other foliage-plants. The glare of color was too dazzling to please, and no arrangement of the plants, so stiff and formal as they usually are when grown for exhibition, can have a pleasing effect without the aid of some greenery as a foil to the color and some graceful foliage to relieve their harsher outlines.

A similar lack of toning material was even more evident in the lower hall, in which the cut blooms were regularly disposed in vases. The most beautiful object here was an immense vase filled with flowers of the finest quality, representing a large number of the choicest varieties, from Mr. J. Brydon, gardener to John Simpkins, Esq., of Yarmouthport. Messrs. Montgomery, of Waban, and E. A. Wood, of Newton, supplied an abundance of cut flowers, which carried off most of the best prizes. Messrs. Brydon, Galvin Brothers, of Boston; James Wheeler, gardener to Jos. H. White, Esq., of Brookline, and Laurence Cotter, gardener to C. V. Whitten, Esq., of Dorchester, were among the most successful competitors, and some excellent flowers, of the leading varieties, were exhibited by Mr. A. H. Fewkes, of Newton, and Mr. Hatfield, the latter's bloom of Etoile de Lyon being without a rival in the show. Mrs. Jerome Jones, as seen at this exhibition, is a very attractive variety, and it is likely to be one of our most popular Chrysanthemums.

Seedlings were quite numerous, and comparatively few of inferior quality now find their way to the exhibition tables. Mrs. F. L. Ames, a very large, partially reflexed flower, from Messrs. Pitcher & Manda, of Short Hills, New Jersey, was awarded first prize as the best yellow. Mr. Brydon's Snowflake, large pure white, with straight florets, was the best of its section, and it was honored accordingly. The best pink, Carrie Bell, of an exquisite tint, was contributed by Mr. J. Eaton, Jr., of New Bedford, and the best red, Oxblood, by Mr. G. B. Gill, of Medford. Clarence, a large orange-red, exhibited by Mr. Eaton, was the best of any other color in competition. A certificate was given to Mr. C. D. Kingman for Nemasket, a large and very perfect flower of pure white color, with a slight tinge of pink in the outer florets.

Some very promising unnamed varieties were exhibited by Mr. Hatfield and the Messrs. Pitcher & Manda, and there were a few exceptionally good named kinds in the New Jersey firm's lot, notably Miss Madge Clarke, deep pink; Mrs. Henry Graves, pale pink; Mrs. Leslie D. Ward, orange-yellow; Mrs. Walter Cutting, creamy white, tipped pink, and Mrs. W. P. Hinzay, bright red. Mrs. J. W. Crouch, exhibited by Messrs. E. G. Hill & Co., of Richmond, Indiana, is a good incurved flower of purplish color.

The principal miscellaneous exhibits were Carnations, Begonias and *Strelitzia Reginae*, from various parties, Roses from the Waban conservatories, and a vase of the new Rose, Ameri-

can Belle—an excellent sport from American Beauty, with flowers of a lighter shade—from Mr. John Burton, of Chestnut Hill, Philadelphia. Mr. Burton's Rose was awarded a silver medal.

Chrysanthemums at Philadelphia.

THE autumn flower-show at the hall of the Pennsylvania Horticultural Society last week was universally pronounced one of the best ever held there, and was remarkable for fine plants, even at Philadelphia, while the cut blooms were very numerous and of good quality. The Japanese type prevailed to the exclusion of the Chinese and the Pompon, and but one specimen of the Anemone-flowered form was noted, a good yellow, Ada Strickland. Six flowers of this variety were conspicuous by their striking contrast with the rest of the exhibition. The first prize for the best vase of twelve white blooms was awarded to Ivory, which has held best place here for several years. The exhibitor was Fred. R. Sykes, gardener to Mrs. G. Dawson Coleman. Mrs. M. J. Thomas, shown by Pennock Bros., a cream-white, very large flowers, with broad, flat, waxy leaflets, took second premium. It was a matter of local pride that these varieties were both originated by Wm. K. Harris. The third premium was taken by Mrs. C. I. Thompson, grown by Thomas Monaghan. The new white, Mrs. Robert Craig, was exhibited by Robert Craig; it is much like Ivory, but smaller. For the best vase of twelve pink flowers David Cliffe took first premium with some excellent blooms of an unnamed seedling. Second premium and a certificate of merit were awarded to Miss Sue T. Price, a clear bright pink seedling of medium size and true Japanese form, exhibited by Robert G. Carey. Each petal of this variety stands out straight, making a well-formed globular flower. The color is pronounced even better than that of Mrs. J. N. Gerard. Maud Dean, grown by Robert Craig, received third prize. Hugh Graham received first prize for twelve yellow flowers with a vase of E. Hitzeroth and A. E. Weidener, good specimens of which were frequent in other classes. H. E. Weidener, exhibited by Robert Craig, received second premium, and twelve blooms of Eldorado, shown by Thomas Monaghan, took third prize. Among other notable yellows not in this class were the strikingly beautiful flowers of Lewis Childs' Madeira, or Golden Ball, and the new Mrs. John Gardiner, from Robert Craig, winner of the Gardiner cup. For the best vase of twelve flowers of any other color, Mars, exhibited by Hugh Graham, took first premium. Second premium in the same class to Mrs. A. J. Drexel, exhibited by Robert Craig, and third premium to Thomas Monaghan for Black Beauty, a large very deep crimson, a flower which was shown by Mr. Monaghan in very good form at New York, beside Goliath, another remarkable seedling of his.

The habit of stems and character of foliage were considered in all the cut exhibits, and all cut flowers were required to have stems not less than twelve inches long. Tall glasses and vases were used throughout, there being but one exhibit on an exhibition board, and this was a selection of twenty-eight remarkably fine flowers from Judge Benedict's place on Staten Island, Wm. Tricker, gardener. Hugh Graham received first prize for fifty-two blooms, one of a kind. The flowers were excellent, with long stems and generally well-known varieties. A notable white among them was Marguerite Graham. Hugh Graham also took first prize for a vase of fifty cut blooms with very long stems and good foliage. H. G. Standen was awarded first premium for twenty-five cut sprays in vases, one of a kind, and for twelve naturally grown sprays, twelve varieties. Ross-trevor, a seedling, shown by Hugh Graham, received a certificate of merit. The flowers are large, bronzy yellow, although they seemed dull beside Golden Wedding. This flower, which last week took three prizes in as many classes in New York, while a little past its best, was the sensation here as at Madison Square Garden. The deep golden color contrasted to great advantage with the lemon-yellow of E. Hitzeroth and A. E. Weidener. It was not entered for competition, but was declared by the judges to be the best yellow variety exhibited to the present time. A silver medal was awarded to Golden Wedding last year at Philadelphia.

A very notable large delicate pink new seedling, Pink Pearl, grown by John N. May, was one of the best Chrysanthemums at the exhibition, and is spoken of as the probable successor to Mrs. J. N. Gerard. It received a silver medal. Fascination, a creamy white, is another seedling of Mr. May's, and received a certificate of merit; Farview, a good amaranth, grown by Wm. Tricker, was also awarded a certificate of merit. Among other new seedlings in the cut-flower class was Leila, a large loose delicate pink, not a marked gain in color; Mars, grown by Hugh Graham, similar to Cullingfordi, but larger, though

it does not appear to be as bright. It is well worth further trial. For Mrs. Craige Lippincott, Hugh Graham received a silver medal.

Among many seedling plants having points of merit George W. Childs Drexel, a good pink with long reflex-twisted florets, grown by Mr. James Verner, took the Blanc prize for the best seedling of 1892. Mrs. James W. Paul, Jr., a well-grown plant from Robert Craig, bore very large incurved pink flowers. A good amber-yellow, identified as No. 12, was grown by Wm. K. Harris. Another unnamed flower of a pleasing plum color, and John Goode, were also seedlings of Mr. Harris. John Goode is one of the best of the new flowers, a beautiful lively pink, maturing to a deep cream or delicate yellow at the centre, and of medium size.

Ten specimen plants grown by James Verner, gardener to A. J. Drexel, at "Runnymede," were marvels of cultivation in the number, size, and coloring of flowers. They were declared the best plants ever shown in Philadelphia, and included Puritan, Robert Bottomley, Miss Minnie Wheeler, Wm. H. Lincoln, Roselyn, Cullingfordi, Hicks Arnold, Frank Thompson, Mrs. Irving Clark and Mrs. A. J. Drexel. The last-named is the seedling shown for the first time in 1891, by Robert Craig. It is a deep rich crimson, of an unusual tone. Second prize for ten plants was awarded to J. Wm. Colflesh. John McCleary and W. K. Harris took prizes for similar collections.

A plant of Mrs. A. J. Drexel was awarded first prize as the best plant exhibited. A specimen of George W. Childs was almost equally fine, and its intensely bright crimson flowers, with golden reverse, were striking. W. H. Lincoln showed still among the best yellow-flowered kind, and there were remarkably good plants of Kioto, the new Mrs. Maria Simpson and Mrs. John G. Whilldin.

For the best three plants introduced to commerce during 1892 the Clothier prize was awarded to James Verner for Mrs. Robert Craig, H. F. Spaulding and Mrs. J. Eyermann. There were many classes and arrangements deserving special mention, as a double row of fine yellow plants of the best varieties in the front of the hall; a collection of six new varieties by W. K. Harris, and a large collection of hardy evergreens from Samuel C. Moon, Morrisville. On the stairway and in the halls on the upper floor evergreens and autumn leaves were tastefully arranged, and brought into relief against draperies of pink and white. The decoration of four tables was heavy and ungraceful.

A number of standards were shown, but no single-flowered specimens, and the collections of tropical foliage and flowering plants, which have been a feature of previous years, from Mr. George W. Childs, Mr. Henry F. Dreer, Mr. A. Blanc and Pitcher & Manda were greatly missed.

Of the six large decorative specimens sent by Miss M. L. Baldwin (Wm. Joyce, gardener) three received the first premium. Mr. Thomas Long, city gardener for Mr. Drexel, had twenty-five magnificent foliage-plants. His collection of twenty-five Ferns was unsurpassed, and every one was noteworthy. Robert Craig's group of glaucous Araucarias and Crotons and Mr. Charles D. Ball's commercial exhibit of foliage-plants were good, as they always are.

Of the Carnations, the large loose Lamborn, with its deep calyx, and Indiana still larger, were admirable whites, although Lizzie McGowan seemed altogether the best Carnation of this color which is grown near Philadelphia. Edna Craig seems to be holding a good place over Grace Wilder, being larger, with firmer stems and an admirable keeper. This variety took the first prize for a pink flower, while among the yellows Buttercup remained the best. Several new seedlings of promise were shown, and prizes, besides those noted, were taken by H. E. Chitty, Edwin Lonsdale, W. R. Shelmire and Griffin Bros.

A large beautifully arranged vase of the new Rose, American Belle, was shown by John Burton, of Chestnut Hill. It is a distinct gain in color, and its early habit makes it specially valuable. The clear pink of freshly cut flowers fades out a delicate pleasing shade instead of the undesirable blue or lilac which American Beauty takes on at that stage. It attracted as much attention as it did in New York.

Pennock Bros. and Joseph Kift & Son received prizes for the Meteor Rose, brought to this country some years ago through the gift of Mr. Henry Bennett to Charles F. Evans, and which at first was not grown with success. It promises to be a favorite here, as it already is with Mr. Pierson and other leading growers about New York. Mrs. W. C. Whitney, grown by John N. May, and similar in form and delicious fragrance to the once popular Francis W. Bennett, received first premium offered for the best six blooms of a new Rose. Other varieties, of which remarkably fine specimens were shown, were Madame

de Watteville, Sunset, Bridesmaid, Perle des Jardins, Madame Cusin and La France.

About \$3,000 were distributed in prizes.

Notes.

According to the *Journal of Horticulture*, one of the most interesting of late introductions among Ferns is the variety *Imbricatum* of the true Maidenhair (*Adiantum Capillis-Veneris*). It is not only very hardy, but the writer ventures to call it a miniature *A. Farleyense*. It certainly will be a treasure if with hardiness it combines the airy grace of a *Farleyense*.

One of the brightest in flower of the new Cannas is *Alphonse Bouvier*, which was shown in admirable form by F. R. Pierson at the Madison Square *Chrysanthemum* show. The large flowers are so brilliant that even *Madame Crozy* looked dingy beside them. *Sarah Hill* was another variety of peculiar brilliant tint, while *Capitaine P. de Zuzzoni* is an admirable yellow.

The *Revue de l'Horticulture Belge* recommends the following mixture as being the best fertilizer for ornamental-leaved *Begonias*: Superphosphates, 33 parts; nitrate of potassium, 17 parts; nitrate of soda, 25 parts; sulphate of lime (gypsum), 25 parts. Pots which hold a litre (four-inch pots) require about two grammes, say 31 grains, of the mixture, and others in proportion.

A gigantic *Camellia* is growing near the royal castle at Pillnitz, near Dresden, Germany. The tree is twenty-four feet high, and produces annually at least 50,000 blossoms. It is supposed to have been imported from Japan about a century and a half ago. It is planted in the open ground, but every winter a structure of boards is built around it to keep out the severe cold of winter.

Mr. Wm. M. P. Bowen, a member of the national Committee upon the Improvement of Highways, has written a circular to citizens of Rhode Island in regard to the subject, in which he states that half a million dollars a year would hardly cover the annual loss and waste which the people of Rhode Island suffer from bad roads, and that this loss amounts to an annual tax of about two dollars upon every inhabitant of the state. If this tax were saved, in two or three years it would pay for putting all the main roads in Rhode Island in first-class condition.

The magnificent *Sabal Blackburniana* which has been for many years a feature of the Ghent Botanic Garden and was one of the finest Palms of its kind in Europe, has been cut down. Its height was fifty-five feet eight inches, its fronds more than six and a half feet across, with petioles nine feet long. It was destroyed because the old, dilapidated glass-house which covered it is to be replaced by a smaller and more strictly utilitarian building, and its destruction is pronounced an act of vandalism by the European horticultural journals.

The tallest trees in the world are found in the gulleys of Victoria, one of which is 471 feet high. Nearly every county in England has its favorite Oak, the largest of which is the *Cowthorpe*, of Yorkshire, which has a circumference of eighty feet. The *Carnoch Ash*, in *Stirlingshire*, is thirty-one feet in circumference. The *Tortworth Chestnut*, in *Gloucestershire*, was used to identify the boundary in the year 1135. It is said to have been the first tree that was ever planted in Great Britain by man. The largest Cedars in England are at *Clumber*; they measure twenty-seven feet in circumference. There is a *Yew-tree* at *Crowhurst*, in *Sussex*, thirty-three feet in circumference. The "*Crawley Elm*" is sixty-one feet in girth. The largest *Beech-tree* is to be found in *Cornbury Park*, *Berkshire*, and the largest *Sycamore* is at *Cobham Park*, with a circumference of twenty-six feet.

A new feature in the construction of greenhouses has recently appeared in Europe. Mr. *Falconnier*, an architect at *Nyon*, *Switzerland*, has invented a hollow brick, which is made of glass. These bricks are not only capable of being used in greenhouse construction, but there already exists a house in the park *Tête d'Or*, at *Lyons*, *France*, in which such bricks have been used in connection with iron for the arches of the frame-work. The bricks are used as ordinary bricks would be, and are fastened together either with lime, cement or plaster. They are translucent, and are blown in the same manner as glass bottles are, in order to make them hollow. They are 20 centimetres long, 14 centimetres wide and 115 millimetres thick (say 8 inches long, 5.5 inches wide and 4.5 inches thick), and sell for twenty-four francs a hundred; this price, however, could be much reduced in case of a growing demand for them.

In the course of a discussion which is going on in the English horticultural papers about stands for showing *Chrysanthemum*-blooms, the *Gardeners' Chronicle* prints an illustration of some *Chrysanthemums* exhibited on boards in Tasmania. The flowers looked just like the best ones in an English or an American exhibition, and they show, as the editor of the *Chronicle* remarks, how well flowers can be grown on the opposite side of the planet. He adds, however, that these people in the colonies would render a much greater service to horticulture by developing their native flowers than by slavishly imitating European customs; and Tasmanian flowers are singularly beautiful. This is a bit of advice which the world has taken a great time to learn. Many of the beautiful Japanese plants which have been sent to this country by Mr. *Hogg* were found growing wild and were neglected by the Japanese themselves, while their gardens were filled with plants from China and many other exotics brought there by Dutch traders.

For many reasons trees taken up late in autumn may be in better condition for setting out than such as have been removed earlier, and if they are heeled in by burying the roots and part of the stems they will be better prepared for setting out in spring. Their value next year will depend largely upon the treatment they now receive, and therefore these precautions, which are noted in the *Country Gentleman*, should always be observed. The ground selected should be dry, well drained and free from stones, so that the soil in contact with the trees can be finely pulverized. No stones, clods, sods or weeds should be used. Dig a pretty shallow trench, place the trees in an inclined position, and not massed so closely as to prevent the fine soil from penetrating every part and leaving no unfilled interstices. When they are well covered smooth the whole with a rounded surface, and if there is any danger from mice dig a flat trench around the whole ground occupied by the trees, so that they may be within and protected by an inclined bank of smooth earth, up the sides of which the mice will not undertake to ascend under the snow.

In the October number of the *Proceedings of the Royal Geographical Society*, of England, there is an interesting article on British Guiana by Mr. E. Im Thurm, who, for the past ten years, has been administrator of the north-western region of that country. This region, he says, falls naturally into two divisions—the upland savannahs, a dense belt of forest, which in some places is more than a hundred miles in breadth, and the low mangrove-swamps along the coast. The only method of communication is by water, the many rivers being connected by a very extensive network of narrow natural streams and artificial canals. In the forest-belt these water-ways are like verdurous tunnels, into which the sun never sends a direct ray, although they are enlivened by innumerable torches of bright color in the shape of epiphytal Orchids, immense butterflies and myriads of humming-birds. The Indians live much in the same way as they did before the days of Columbus, although their old local customs and habits now bid fair to disappear as the country is opened up in the search for gold. The extraordinary fertility of the soil is illustrated by the fact that in his own garden, which was drained and cleared hardly more than two years before he wrote, there already stand avenues of trees (*Casuarina*) forty feet high, which he then planted.

In some parts of the country this year where apples are very abundant they are shipped away by the car-load to be turned into cider. All sorts are used—winter apples and fall apples, ripe and unripe, large and small, sweet and sour—and all are mixed together and sold at the same price, as if one apple was as good as another for cider. In France, although it is the home of the vine, much more attention is given to cider-making than is done in this country, and the different varieties of apples are classed according to the abundance and quality of the juice they yield. Years ago certain kinds of apples were largely planted here on account of the quality of cider which they yielded, principal among these being the *Harrison* apple, a little, hard, green, late autumn fruit, which was very juicy and of a special acid flavor. These apples were mixed sometimes with the *Campfields*, which gave a rich, sweet juice. The *Gardeners' Chronicle* for the current week has classified from the *Herefordshire Pomona*, a list of apples which are considered the best for cider in England. One of these, called the *Devonshire Royal Wilding*, is said to produce cider which as long ago as 1753 brought five guineas a hogshead, when ordinary cider brought but twenty shillings. It is rather remarkable that although there are a few varieties in this country which are esteemed especially good as vintage fruits, very little prominence is given to this quality in general descriptions of apples, new or old.

GARDEN AND FOREST.

Horticultural Education.

WHILE scientific papers in Europe are discussing the value of systematic schooling in horticulture and agriculture, and while many doubts are expressed as to whether there is any proof that such training has ever been a practical help to farmers and gardeners, schools of agriculture and horticulture are multiplying in almost every country in Europe, and the instruction given in the older ones is growing more broad and more thorough—that is, more truly scientific. In our own country it must be confessed that the agricultural colleges in many of the states make a very poor showing both in the matter of attendance and training. The colleges in a few states, however, have already become centres of influence and places to which farmers and gardeners turn with confidence when they wish for help or enlightenment. It is the college entomologist to whom the farmer sends specimens of destructive insects for identification, and the professor not only gives the enemy's name, but explains how he may be defeated. It is the mycologist of the same institution who is consulted on plant diseases, and its chemist who answers questions about soil and fertilizers; and in this way a vital connection has been established between the farms of the state and its college laboratories. Where such relations have grown up there is no question as to the advantage of scientific knowledge and training to all who cultivate plants for ornament or use.

Of late years the practice of furnishing short courses in agriculture has been growing among the colleges, and several of them now offer such privileges to meet the needs of students who have only the time or means to spend a single term, or perhaps two terms, at the university. A circular just received from Cornell University outlines a short course which has just been opened there, which consists of studies partly prescribed and partly optional. Attention must be given to agriculture five hours each week and to chemistry three hours, and the studies in these regular

hours are on fundamental subjects with which every one should be familiar, whether his field of practice is the garden, the orchard, the greenhouse or the farm. Besides this, there are optional studies, such as entomology, botany, dairy husbandry, animal industry, poultry-keeping and the like, in which practical exercise is given in specific branches. We are especially interested, however, in the optional course in horticulture, which offers, in the first place, instruction in fruit-culture with practical work in the best methods of pruning, training and planting, and the determination and discussion of varieties, with the advantage of an admirable collection of orchard-fruits and small fruits for study and practice. Vegetable gardening is also taught, and includes practical work during the winter in the forcing-houses, where Tomatoes, Cucumbers, Mushrooms, Beans, Lettuce, Radishes and other plants are grown as winter crops. The propagation of ornamental plants and floriculture embraces practice in all methods of reproducing plants, from the sowing of seeds to the making of cuttings, budding and grafting. Instructions here are given in the laboratories, which are greenhouses designed for propagating purposes. Lectures and demonstrations are also given in the management of ornamental plants together with practice in the preparation and application of all the remedies for insect and fungous diseases.

The latest attempt to popularize instruction of this sort comes from the Agricultural College of Pennsylvania, which just announces what is called an "Agricultural Chautauqua," which provides for a course of home reading upon agricultural and horticultural subjects to be pursued under the general direction of the college. This course covers three groups of subjects—agriculture, animal husbandry and horticulture—and under each group five standard books are selected which are to be read by students. For those who desire to do more than this a system of home examination has been provided, and readers who pass a satisfactory examination upon a group of five studies will receive a certificate, and a satisfactory examination upon two groups will entitle one to a diploma. This course is free to every one and leaves the student the fullest liberty as to the choice and order of subjects and the amount of time devoted to them. It is thought that even one hour a day, if faithfully used, will enable a student to accomplish very much in the course of a year, and much more time can be devoted to it by those who have the leisure and the inclination. A serious drawback to success in this scheme is the lack of trustworthy text-books. Nevertheless, such a course of reading must prove stimulating and helpful when the text-book does not become a substitute for personal observation, but by dealing with and illustrating the materials and processes of every-day life on the farm is a direct encouragement to study the things themselves.

It is not probable that any finished gardeners will be turned out in a single term at Cornell, while a certificate, or even a diploma, from this novel Chautauqua would hardly pass current as a guarantee of high proficiency. There is little doubt, however, that the addition to ordinary business practice of a short college course or a systematic course of home reading would be of distinct value to any young man, or any young woman either, for the matter of that. Not only will such a schooling make better horticulturists, but it will enable a great many more young people to pay some attention to the scientific basis of the art of horticulture. What is most needed for a higher horticulture, and an improved agriculture as well, is a body of men devoting themselves to original investigation; and while these short courses will never equip men for such high service, they will help to enlarge the class from which such experts must be drawn. It is an impossible state of things to have a few trained and finished horticulturists in the country while the general average is extremely low. Men of the first rank in science and practice are not developed out of such conditions. There must be a constant gradation from the lowest to the highest, so that the more

persons there are who have some training, who realize its value and are ambitious for more, the more there will be to rise from this class by natural selection to the highest rank of skilled scientists. The broader the base of the pyramid the more lofty will be its apex. While these courses, therefore, are beneficial directly in the instruction which they give, they render a higher service by increasing the material from which the very best are drawn. The greater the number of good practical men we have in our farms and gardens, who are also keen observers and eager learners, the more there will be to rise to broader attainments in knowledge and superior skill in practice, and the more certain will be the supply of scientific students, experimenters and explorers of the first rank upon whose patient work the hope of our agriculture and horticulture must ultimately rest.

A German Pleasure-ground.

THE issue of *Gartenflora* for October 15th contains an interesting illustrated description of a peculiar pleasure-ground, called the "Rheinanlagen," which lies along the right bank of the Rhine at Coblenz. When the late Empress Augusta established herself at Coblenz in 1850, her husband, the future Emperor, being then Prince of Prussia and military governor of the district, the ground now covered by this park was chiefly waste land interspersed with hillocks and a few bits of meadow. Her attention was soon attracted by the neglected spot, with its beautiful views of the river, and through her efforts, and largely in accordance with her own ideas as to how it ought to be arranged, it was gradually transformed into the very pretty pleasure-ground of to-day. It measures nearly two miles in length, with an average breadth of only some four rods, some ten feet of which is absorbed by a towing-path skirting the water, for the convenience of the drivers and teams which must drag up stream the clumsy traffic-scows which drift downward with its current. This path, however, along the confines of the park has been handsomely built, and is much frequented by the public toward evening, when the tows have tied up and the opposite western shore of the stream is already in shadow. A small spot has also been reserved for the use of the military Pioneers, whose pontoon practice-ground is on an island near by. Nevertheless, skillful treatment has done wonders in beautifying this narrow strip of land. Its narrowness, of course, prevented any attempt at extensive plantations or large showy flower-beds. It was wisely decided to make its chief feature a long avenue running parallel with the Rhine. This avenue is planted along half its length with Lindens, and along the other half with Plane-trees and Chestnuts, and forms first a carriage-way for about one-third of the length of the pleasure-ground, and leads to a pretty restaurant, after which it is a foot-way lined with ornamental benches. On either side of it, as the width of the ground permits, are small and varied masses of shrubs and flowering plants.

At one end the confines of the ground are marked by a tall column, crowned by the imperial eagle, and at the other by the abutments of the railroad-bridge which crosses the river, masked by a thick group of trees. Near these is a pretty plantation of conifers and a little Rose-garden; and, as the pictures show us, architectural and sculptural adornments have been tastefully introduced at many points to vary the aspect of the grounds. Here we have two large arches, springing near the balustrade with rises above the towing-path, covered thickly with vines, and forming effective frames for the pretty picture made by a village on the opposite shore of the river. Then we see a projecting platform with a flight of steps leading down to the towing-path, and encircled by an iron railing, the piers of which, however, are of stone and bear charming little statues. And, again, at the edge of a luxuriant mass of shrubs stand four statues of children playfully simulating antique gods, which are connected by a low plinth that gives architectural effect to the intermediate flower-beds it encloses. There

are also a little observatory for those who are not satisfied by the perpetually changing and perpetually beautiful glimpses of the river which the ground itself affords, several prettily designed shelters, and an ornamental grove hidden away in a thick shrubbery, while occasional large trees give an air of dignity to the whole. Indeed, the newest portion of the pleasure-ground, laid out some fifty years ago, is covered with woods and naturalistic architectural decorations.

When one reads how much has been done on so narrow a bit of land as this, and how much refreshment and delight it gives to thousands of people, our own neglect of otherwise useless pieces of ground seems doubly regrettable. Of course, the close vicinity of the noble river plays a major part in the beauty of this garden; but we have hundreds of towns lying on the shores of fine rivers, and it seems as though in each and every one of them a narrow strip of ground might be secured, which, tastefully arranged, would be of priceless value not only to the appearance of the town but to the bodies and spirits of its population. No matter how small it may be, a spot can be made varied and lovely by an artist's hand and there are often better possibilities in a long, though very narrow, strip than in a square one covering an equal area, especially if it lies along the borders of a sheet of water. Even the fact that the water's edge must not be shut off from practical public service need not be a fatal blot on an adjacent pleasure-ground, as is shown by the example of the one which the Empress Augusta treated.

Notes of a Summer Journey in Europe.—XVII

IT is probably not too much to say that no private nursery or horticultural establishment in the world has done much for the advancement of horticulture, in all its branches during the last fifty years, as that of Messrs. James Veitch Sons, proprietors of the Royal Exotic Gardens at Chelsea and those at Coombe Wood. The fifth generation of the name have now entered the business, which is still carried on with all the energy and enterprise characteristic of the firm in the past and with a greater prestige than ever. The Veitches have been indefatigable as collectors, sending agents to all available parts of the globe where there was any chance of finding new plants for use or ornament. Members of the firm have themselves gone on these expeditions, and every active horticulturist knows of or has benefited by the collections of late John Gould Veitch, made in Japan and Australasia over thirty years ago. His son, now one of the young members of the firm, started last September for the countries and islands of the Pacific on a collecting trip, which is expected to last two years. The firm is not, however, merely known as collector and distributors of rare and new plants, for it carries on a system of hybridizing, cross-fertilizing, testing, etc., worthy of any horticultural school or specially endowed institution, and indeed, the results obtained are far ahead of many institutions of which this work would naturally be expected.

Besides the nurseries already alluded to, there are the grounds and nurseries at Fulham, Slough and other points, the traveler on the railway from London to Kew passes by on their stations at Turnham Green. In the matter of publications, too, the firm is not satisfied with perennial catalogues and price-lists, but has issued other publications which are valuable monographs to all cultivators. Among these the *Manual of the Coniferae* stands as an extremely useful hand-book of the cone-bearing trees in cultivation up to the time of its publication, eleven years ago; while the *Manual of Orchidaceous Plants*, cultivated under glass in Great Britain, now being issued in parts, is indispensable to every intelligent and progressive Orchid-grower, and even those who have only a general interest in these flowers will find much that is interesting and instructive.

The Royal Exotic Nurseries at Chelsea are the headquarters of the various branches, and the plants grown here are not those which require the protection of glass houses, of which there are considerably over a hundred given up to propagation and cultivation. Such a collection is too great to be fully appreciated in the course of two or three hours, but the traveler who comes here with a hobby for Orchids of any class, Nepenthes, Hippeastrums, Begonias and the gorgeous Japanese and other greenhouse Rhododendrons and Azaleas

re to be satisfied. A great many hybrids have been raised from these, some of them very beautiful. In the latter part of the month hybrids of *Rhododendron Javanicum* and others are showing good bloom. It is a characteristic of this class that they will bloom all the year round. They require considerable heat in winter, but otherwise they are very easily grown and require no unusual treatment. There are almost all colors and shades and combinations of colors in the flowers, while there are a number of good double forms. These *Rhododendrons* are generally considered more beautiful and more active than the *Camellias*, which are not neglected here. Great stocks of the most useful decorative plants are kept, and these must be seen to be appreciated.

The visitor especially interested in hardy trees and shrubs would do well to go to Coombe Wood, where there is a rich collection; even the ordinary sightseer or lover of things beautiful must derive a great pleasure in going about this beautiful country and in visiting a nursery so trimly kept and so filled with fine specimens of plant-growth. The nursery is largely situated in a road, sheltered hollow, and to look down upon this in June, when the *Rhododendrons* and many other shrubs are in bloom, must be a sight well worth going a long way to see.

Conifers are a specialty here, many of them having been first introduced into cultivation through this establishment. Among these are the beautiful *Abies Veitchii*, *A. Sachalinensis*, *A. brachyphylla*, the curious and interesting *A. bracteata*, *A. polita* and many others. Japanese Maples have been introduced in great variety, and there are some of the originally imported specimens, which have attained handsome proportions. [A. Veitchii, and perhaps others of the trees named above, had been sent to America by Thomas Hogg or his son before they were introduced in Europe.—ED.]

In such a climate as this, with winters so much milder than are accustomed to in southern New England, it is possible to grow a greater variety of shrubs out-of-doors, and plants in New Zealand and Chili and other temperate parts of the world thrive well. One of the most interesting and beautiful of these is *Eucryphia pinnatifolia*, a native of south Chili. It has proved quite hardy at Coombe Wood, its hardiness being attested by fine bushes eight or nine feet high, just out of the bloom borne during July and August. This shrub has deep shining green pinnate leaves of fine leaflets, and its flowers, which expand from two to three inches across, are composed of four broad white petals, numerous long silvery white stamens and reddish brown anthers. They strongly suggest large *Hypericum* or *Stuartia* blossoms. This would be a most desirable acquisition among shrubs for planting south of Washington. The species is, as yet, a great rarity in cultivation, and it is for their enterprise in making such plants better known that the fame of the Veitch establishment is largely due. Although the climate here is so much milder in the winter than in any part of New England, there are some disadvantages to offset the moderation. This is perhaps particularly the case with *Firs* and other plants from northern regions, which do not flourish well in this part of England, because the warm winters and early springs interfere with starting into growth too soon and with consequent injury by frosts, occasionally as late as June.

The raising of shrubs for forcing purposes has grown to be a large business here. Lilacs, *Viburnums* and *Azaleas* are grown in quantities and are superior to those imported from the Continent. A large number of small plants of the handsome Japanese *Tecoma grandiflora*, in pots, were coming into bloom in mid-September. Our *Fringe-Tree* (*Chionanthus virginica*) is grafted on the European Flowering Ash (*Fraxinus excelsior*) and is used as a pot-plant for forcing; thus treated it flowers beautifully in winter.

Plants of the true *Actinidia polygama* are growing here, but only ones of which I know besides those recently noticed in GARDEN AND FOREST (vol. v., p. 320), on the grounds of the cultural College at Amherst, Massachusetts, and which were brought from Japan by Professor W. P. Brooks. The beautiful silvery lustre which covers a portion of the leaves is an efficient means of identifying the species, and if further proof is necessary, it is to be found in the fact that at Coombe Wood much trouble is experienced from cats, which destroy the foliage within reach. The attraction which this plant has for cats is remarkable. A Japanese gentleman informed me in order to capture all the cats of a neighborhood, which was wild or Bohemian life, it was simply necessary to burn the leaves of the *Actinidia*, when all within range of the odor would be so effectually attracted as to be caught with the greatest ease.

The Messrs. Veitch do not confine their work to any one particular line of horticulture, but deal extensively in fruit,

vegetable, flower and other seeds, plants and bulbs, among which they carry on numerous experiments. Thus equipped with the best of material in all branches of the business, they are enabled to furnish an estate completely from their own stores, and as they also undertake all kinds of planting and landscape-designing, there are not a few English estates which are conducted entirely under their management.

Arnold Arboretum.

J. G. Jack.

Color for the Lawn in November.

ONE of the sorrows of winter is the absence of color in the landscape. It was this fact that led to the planting on the lawn, in a conspicuous view from our living-room windows, a *Hemlock-tree* as a background for the *Witch-Hazel* and *Waahoo*, which give late blossoms and bright berries. Together they make the prettiest imaginable group. The frost may come, the snow may fall, but all the cold white days we look into the heart of a little summer. The yellow stars of the *Witch-Hazel* twinkle and shine well into November, and the *Waahoo* berries hang on the boughs through the winter. They are both native shrubs, and thus are perfectly acquainted with our climate. They give great pleasure to the children of the household, who become quickly interested in what seems their untimely blossoms and fruit. In choosing plants and trees for the home lawn the children's interests deserve consideration.

The *Witch-Hazel* is a true witch among shrubs. It has a wild way of growth, several crooked branching trunks growing from the root, smooth leaves, four very long, linear petals, yellow and twisted or curled. So far it is not unlike other shrubs. The name *Hamamelis* indicates its most striking peculiarity, "flowers and fruit together on the tree." It blossoms in October and November, and the flowers of this fall will be the fruit of next fall, which hangs on the bare boughs when it next blossoms. The flowers, though small, are made noticeable by the manner of blossoming in clusters on the stem. The fruit is a woody capsule, nut-like, two-celled, and the seeds, almost black and shining, are the prettiest seeds in the world. Another peculiarity of this curious shrub is its explosive seed-scattering. Many years ago, wishing to secure a quantity of these seeds to make a necklace like one I had seen, it became a question how to get them. Before the nut was ripe enough to open, it was almost impossible to get at the seeds, and when the capsule opened they were shot out suddenly, scattered far and near and lost. A quantity of the almost ripe seed-pods were gathered, put in paper bags and hung up to wait and see, or rather to wait and hear, what would happen. For days those pods, as they dried, kept popping in the bags, and the seeds, small and polished, very like rice in shape, were secured. The explosive opening of the wild *Witch-Hazel* fruit may be known to all, but it is not very long ago W. H. Gibson, in "A *Witch-Hazel* Copse," tells of making this discovery after he was sure he knew everything about the *Witch-Hazel*.

But when the seeds were gathered there was another problem to be solved—how to thread them. The finest, sharpest needle would split them every time. The friend who had threaded them told me how it could be done. The seed was to be cut off at each end with a very fine file. This was a labor of love, and the necklace was pretty enough to pay the trouble. Like the flower, the leaves when ripe are yellow. To those who enjoy the autumn woods it is a very bewitching shrub, but never seems more witch-like than when seen against a bit of blue sky. The leafless branches, lifting up clusters of twinkling lights, have a fascination for eye and heart.

The *Waahoo*, *Burning Bush*, *Spindle-tree*, *Prickwood* or *Strawberry Bush* belongs to the *Staff-trees*. Perhaps it was early found out that a branch of the shrub made a good stout staff. Some of the numerous names have come from the uses to which the wood has been applied. The common name, *Spindle-tree*, came from the fact that in the days of spinning-wheels the wood of the European species was used to make spindles, and the name remains. Possibly the shrub is called *Prickwood* because the wood was used in making skewer-like pins, used to hold the dress together as late as the reign of Henry VIII., when metal pins became more general. The fine hard-grained wood is used for the finer articles of turnery, and was formerly used in making musical instruments. The European *Spindle-tree* is often grown in shrubberies, but it is in no way superior in beauty to our native *Waahoo*, with its interesting Indian name.

The *Waahoo* blossoms in June; the flowers are small and not particularly attractive. It is common enough all summer, but when the world is bereft of color, then the *Waahoo* is

in its glory. The bright crimson fruit, drooping on long peduncles, continue on the stems through the winter, as grateful to the eye as the Palm of the desert.

New or Little-known Plants.

The Chrysanthemum, Golden Wedding.

IT is the boast of American Chrysanthemum-growers that they are producing home-grown seedlings which average as good, or better, than importations from abroad, and yet we are still receiving varieties from Japan which are of conspicuous excellence. The famous Neesima collection of twelve plants, for example, not only contained Mrs. Hardy, which was then an entirely new departure, but such standard varieties as W. H. Lincoln, Mrs. Fottler, Kioto, Lillian Bird and others. Last year Peter Henderson & Co. imported a variety from Japan from which they secured three or four plants, which flowered in time to be exhibited at the Chrysanthemum show in Philadelphia, where it received a silver medal. It was happily named Golden Wedding, and at that time was described in this journal as a "flower of the largest size, high in the centre, with petals incurved and loosely twisted, while the outer ones are somewhat drooping and reflexed. It is a bold flower of uncommon form and great sturdiness in stem and foliage."

This year the plant has continued to show the same vigor of growth, and in the New York show it was the variety used in successful competition for the GARDEN AND FOREST cup for a vase of the best six blooms of any variety. It was the flower which also won the cup offered by Mrs. W. Bayard Cutting for a vase of fifty blooms of any given variety. It also received a premium as the best yellow flower at the same exhibition. It was again shown in Philadelphia, and, while not entered for competition, the judges pronounced it, in their judgment, the best yellow Chrysanthemum in commerce. We may add that while the flower has great size and substance, it has not a coarse line, and its color, while a pure yellow, is unusually deep and rich. The illustration on page 559 shows the character of the flower, but it does not give an adequate idea of its extraordinary depth. It is so double that it never shows an eye. A large vase in which a number of these flowers are loosely arranged on long stems makes a decorative object of most striking character.

Foreign Correspondence.

London Letter.

CONIFERÆ.—The most successful, and, in some respects, the most important of the various conferences or plant congresses arranged by the Royal Horticultural Society was that devoted to Coniferæ, and which was held at Chiswick in October of last year. The report of the proceedings, which forms Volume XIV. of the Journal of the Society, has just been published. It fills nearly six hundred pages, and is made up of papers contributed by specialists, both scientific and practical, who are eminent authorities on Coniferæ. The botany and scientific aspect generally of the order are dealt with by Dr. Masters, Professor Carl Hansen, Professor Marshall Ward and Mr. W. F. Blandford, the economic and decorative value of the order being treated upon by Mr. H. Veitch, Mr. G. Nicholson, Mr. Malcolm Dunn, Mr. E. J. Baillie and others.

The list of Conifers and Taxads in cultivation in the open air in Great Britain and Ireland by Dr. Masters, F. R. S., fills seventy-seven closely printed pages. The *Genera Plantarum*, of Bentham and Hooker, has been followed as the standard authority for the generic names, and for the species, De Candolle's *Prodromus*, "but with considerable modification." This list will, no doubt, become the recognized authority for the names of Coniferæ, in England at any rate. Of Professor Hansen's paper on the Conifers of Denmark, Dr. Masters, who is the first Eng-

lish authority on Coniferæ, remarks, "nowhere is there collected together so much interesting information as in this paper of Professor Hansen's."

"The Diseases of Conifers," by Professor Ward, is a most valuable contribution to the literature of this order. The same may be said of the whole of the papers which deal with the more practical questions, such as planting, the value of Conifers in the garden, etc. Although called a "Report," this volume is really an encyclopedia of information on Coniferæ, and should be in the possession of every one interested in this most important family of plants.

NEPENTHES.—A well-grown collection of these plants is a most attractive as well as interesting feature in a garden. Unfortunately, it is only in very warm houses and with otherwise exceptional conditions that such a collection is attainable. Messrs. J. Veitch & Sons, of Chelsea, have made *Nepenthes* a specialty for many years, and their collection now is an exceptionally rich one. They have raised numerous hybrids, among them being the best of all *Nepenthes*, species or hybrids, *N. Mastersiana*. A collection of thirty kinds, all beautifully grown and laden with fine, well-colored pitchers, was exhibited by them at the meeting of the Royal Horticultural Society held this week. There were no less than thirteen species among them—*N. Burkei*, *N. Rafflesiana*, *N. sanguinea*, *N. distillatoria*, *N. cincta*, *N. Veitchii*, *N. Northiana*, *N. Curtisii*, *N. albo-marginata*, *N. bicalcarata*, *N. hirsuta*, *N. ampullaria* and *N. stenophylla*. Besides these the best of the hybrids were represented together with a new hybrid, raised by Messrs. Veitch from *N. Northiana* and *N. Curtisii*, and to which they have given the meaningless name *N. Northisii*. It is a beautiful plant, and if it only inherits the constitution of *N. Curtisii* it will become a favorite in gardens. It has broad leaves, the pitchers of the same size as those of *N. Northiana*, and colored better than either of its parents, being nearly yellow, with numerous large crimson blotches and rim. I have never seen a more creditable collection of *Nepenthes* than these.

PANDANUS BAPTISTII is a new plant recently introduced from New Caledonia to Kew and elsewhere, and exhibited this week by Messrs. Veitch. It was shown in the summer by Messrs. Sander & Co. under the name of *P. Dyeriana*. When the Kew plant arrived from Australia it had gracefully arching leaves colored glaucous green and striped with cream-yellow. Under cultivation here, however, it has lost the clearness of its variegation, although the lines, now yellowish green, are still present. If it can be grown to assume the color it had when first imported it will probably become a favorite plant for table decoration. It is, I believe, only a variegated form of *P. inermis*, a well-known variety in botanical collections, and which is remarkable in having elegant channeled glaucous green leaves a yard long and one and a half inches wide, with spineless margins. The absence of spines distinguishes this species from all other garden Pandani. According to some authorities *P. inermis* is the same as *P. lævis* of Rumphius.

CYMBIDIUM WINNIANUM.—This is the best hybrid *Cymbidium* yet raised. It is the result of crossing *C. eburneum* and *C. giganteum*, the latter the seed-bearer, and was raised by Mr. C. Winn, of Birmingham, a well-known amateur grower of Orchids. The plant, which bore five racemes of flowers, is like *C. eburneum* in foliage and habit, and also in the length and curve of its flower-spikes, each of which carried about a dozen flowers nearly as large as those of *C. giganteum*, and colored cream-yellow, with spots of red on the labellum. The plant was exhibited by Messrs. F. Sander & Co., and was awarded a first-class certificate.

SPATHOGLOTTIS VIELLARDII, var. RUBRA.—This is a rich-colored variety of a pretty free-flowering stove Orchid introduced about ten years ago from Polynesia by Messrs. Linden, and at first called *S. Augustorum*. The type has broad plaited leaves and an erect stout scape, two or three feet high, bearing a cluster of whitish *Phalænopsis*-like flowers, which spring from among numerous boat-shaped green bracts. The variety, of which a plant was exhibited

this week by Sir Trevor Lawrence, has rich rosy purple flowers with a deep blood-crimson lip, and is altogether more attractive than the type, good Orchid though this is.

CATLEYA LEUCOGLOSSA is a beautiful hybrid of Veitchian origin, the parents being *C. Loddigesii* and *C. Fausta*, the latter a hybrid between *C. exoniensis* and *C. Loddigesii*. In the soft blush-lavender color of its well-formed flowers and the white front lobe of the labelum this new hybrid has quite exceptional attractions. It is what all garden hybrids should be, a plant which, while combining all the good qualities of its parents, is superior to both. It obtained a certificate.

DENDROBIUM STRIATUM is a Veitchian hybrid of somewhat remarkable parentage, having been obtained from *D. Japonicum*, one of the smallest, and *D. Dalhousieanum*, one of the largest of all Dendrobes. It has rosy flowers not unlike those of *D. nobile*, with a curiously formed lip. It cannot be called an acquisition to garden Dendrobes, though as a hybrid it is probably of special interest to morphologists.

NEW CHRYSANTHEMUMS.—The following were awarded certificates at the last meeting of the Royal Horticultural Society: *W. H. Atkinson*, a fine Japanese variety, described in my last letter; *Vesuvius*, also Japanese, a good decorative flower, large, of good substance and form, its color rich orange; *Golden Ball*, a golden yellow Japanese variety of medium size, raised in the centre, the petals drooping. It is said to be free and a promising plant for cut flowers; *Emily Doone*, Japanese, a large flower, white, the outer petals tinged with rose, the central ones creamy yellow.

Mr. Cannell, of Swanley, sent a tray of twelve magnificent blooms of last year's best production in the way of new Chrysanthemums, *Viviand Morel*, which is a great improvement on the older *Etoile de Lyon*. He also exhibited twelve fine blooms of one of the very finest of all Chrysanthemums, *Colonel W. B. Smith*, which, I believe, we owe to your Mr. Spaulding. It is as grand among the golden-colored varieties as *E. Molyneux* is among the crimsons.

Entomological.

The Oak-pruners.

THROUGHOUT the month of September there were noticeable along the roads in parts of New Jersey and Pennsylvania, broken and dying twigs and branches on Oaks of all species and of all sizes. These became more numerous and prominent as the month advanced, and what was at first regarded as an accident, or as a consequence of the anthracnose, so abundant during the year, proved on investigation to be the result of insect attack, and of an old offender at that. The first noticeable sign of injury was a premature coloring of the leaves; the first high wind snapped the dying branch, often leaving it suspended by a few fibres, dead and dry, until a heavier wind brought it to the ground. An examination of the fallen branches at this time shows that the broken end is clean cut, except for the bark, and that there has been a deliberate girdling from the centre outward, leaving only the bark and a few wood-fibres intact to prevent immediate breakage. In the very centre will be seen, on close examination, a little plug of wood cuttings deceptively resembling plant-pith, and if this is lifted out a smooth hole about an eighth of an inch in diameter is disclosed. If the branch or twig be then

split there will be found, at a distance of from one to two inches, another plug of shavings, and, an inch or more beyond, yet another, or sometimes there will be the end of the gallery. Lying in the burrow between these last plugs, or between the second plug and the end, there will be found a rather deep yellowish larva, with small brown mandibles and a considerably enlarged head and thoracic segments. In this burrow the larva rests quietly during the winter, changing to a pupa in spring. In this pupa all the appendages of the future adult are separately encased, and we readily recognize it as a long-horned beetle, which, when it finally matures, proves to be a species of *Elaphidion*. Two, if not three, species are engaged in this destructive work. All are very much alike, of a chestnut-brown color, sparsely irrorate with pale hair, massed into a more definite pattern on the elytra. The forms of the larva, pupa and imago are very well shown in figure 94.

Ordinarily, the insects are not very abundant, though scarcely rare, and their injury amounts to a somewhat haphazard, and by no means severe, pruning. Even in seasons like the present, where the insect has appeared in unusually large numbers, the pruning is not really excessive; but on shade and ornamental trees it is sometimes scarcely judicious, and, occasionally, decidedly disfiguring. In some of the broken branches, two or even three larvæ were found at short intervals; but there is rarely more than one attempt to girdle. How do the larvæ nearest the extremity of a branch know that there is another, nearer the base, who will attend to severing it? I have also bred the beetles from young Oak stems and trunks as well as branches, the burrows in one case extending beneath the surface. In no instance did any of these trunk-borers make any effort to girdle, though they gave out exactly the same species bred from larvæ that had girdled branches.

I have not been able to satisfy myself whether or not the

Fig. 94.—Larva, pupa and imago of Oak-pruner.

Fig. 95.—Burrows of *Elaphidion* in branches of scrub Oak.

insects usually, or preferably, attack healthy rather than dead or dying wood. It sometimes seems as if they did; but it is certain, also, that they very freely attack diseased or injured branches. In an Oak-brush, through which a fire has run one year, these larvæ will be found in great numbers the year fol-

lowing. In Fig. 95 are shown specimens of the work of the larvæ in a burnt scrub Oak

When these insects have been abundant, the fallen branches should be gathered and burnt during the winter; this will, of course, destroy the larvæ contained in them. When infested Oaks are near orchards this course is imperative, because the insects also attack Apple and other pomaceous fruit-trees.

Cultural Department.

Top-grafting Apples.

THERE are few questions in orcharding so unsettled as that of the effect of the stock upon the cion. In root-grafting and nursery budding it is pretty generally conceded that the effect is nil, or nearly so; but when it comes to grafting or budding on the branches of bearing trees, the general opinion seems to be, among ordinary observers, that some effect upon the size and quality of the fruit may take place. To determine such a question with entire accuracy manifestly would require much more careful, systematic and long-continued tests than we have any account of. I am sure it would be profitable to have a long series of experiments carefully made at some of our agricultural college farms with a view of settling the matter, as in commercial orcharding, especially, it may often be that a right decision would be of large pecuniary importance.

Some of the claims made in regard to these effects have been manifestly untrue. Millions of nursery trees have been sold through our extreme northern states which were stated to be made entirely safe against winter-killing by being grafted upon Siberian Crab stocks. This pretense has disappeared, and the trees sold under it have disappeared almost as soon. Not only were the grafts no hardier, but the Crab stocks proved very short-lived, and, of course, the tops could not survive the roots, even when they were themselves of iron-clad varieties.

I am led to discuss this topic just now by noticing in a report of the Canadian Horticultural Bureau a question put by a member of the Committee of the House of Commons on Agriculture and Colonization to Mr. John Craig, horticulturist in charge of the Dominion Horticultural Experiment Stations at Ottawa. This question was: "If a winter Apple is grafted on a summer Apple, what is the effect?" Mr. Craig's reply was: "The theory is, that it hastens the ripening season and lessens the keeping qualities." But there was no evidence that Mr. Craig indorsed this "theory"; and in my own fifty years of observation and experience in fruit culture I have never seen any conclusive evidence that such an effect had been produced.

Now, this is by no means saying that no effect is produced by such grafting. We are all aware that the grafting or other working of Apples upon the Paradise or Doucain stocks, and of Pears upon Quince stocks, has a decided effect in causing early fruiting of the grafts—usually attended, or followed, by a decided abbreviation of the life of the graft, unless it is so deeply planted as to prevent it from throwing out independent roots of its own. This knowledge is quite in line with what has been referred to above as the result of grafting our common Apples upon Siberian Crab stocks. The life of the graft can be no longer than that of its stock.

It has often been noted and recorded in our journals and books of horticulture that the fruit grown upon trees dwarfed by such methods is often larger and finer than the average of like fruit in ordinary standard orchards. But while this is indisputable, an unsafe conclusion can easily be drawn from it; for with the ordinary orchard culture it will be found that the dwarfed Pears and Apples prove much inferior to those on standard trees; clearly showing that, other things being equal, the dwarfed trees are really of inferior value.

The Doucain stocks being not conveniently attainable, I have for a considerable time been making use of the well-known Tetofsky, one of the first Russian Apples introduced into this country, as a substitute. This variety is not strictly a dwarf, for in rich soil the Tetofsky makes a large tree. Besides this, it is not itself an extremely early bearer; but having about a dozen of them in a row along with a single tree of another Russian—Prolific Sweeting—and finding the last much the most desirable Apple, I top-worked it upon the Tetofskys. The result has been remarkable as well as instructive. The original Prolific Sweeting was received as a single cion from the United States Bureau of Agriculture in 1870. It was root-grafted and has made a fine growth, and is now a large tree, but it has never grown anything like a full crop. Quite different has been the case with its cions worked in the

Tetofskys. They have borne immense crops of very fine apples, finer as well as so much more numerous; but these grafted trees have made but a slow growth, though quite healthy.

Now, here seems to be a very plain case of influence of stock upon cion, nothing very new, because quite in line with our knowledge of what happens when we graft upon Doucain stocks, though in the latter case it is usually done at the crown, while my Sweetings were worked into the branches of Tetofsky.

Influenced by this interesting experience, I have recently been setting a considerable number of Tetofsky-trees, with the view of using them as stocks upon which to work tardy bearers of otherwise desirable Apples. For this section, particularly, the Bethel Apple has shown a very high degree of merit as a commercial fruit, being for the "cold north" very much what the Northern Spy is farther southward—large, handsome, and an excellent keeper of very good quality for all uses. It is, by its looks, quite plainly a seedling of Blue Pearmain, but oval instead of oblate; an excellent bearer, but tardy in beginning to bear.

It just now occurs to me that this use of Tetofsky as a stock might be easily and profitably extended to regions other than our "cold north" for varieties that one must plant chiefly "for his heirs," if grown in the ordinary way. Why not use it for the Spy, for instance? I leave this thought with careful readers; but I must be permitted to say to them, too, that I have neither cions nor trees of Bethel for sale, as it is my experience that this may save much unprofitable correspondence.

Newport, Vt.

T. H. Hoskins.

Basket-plants for Conservatories.

MANY attractive changes of arrangement may be made in the conservatory by the judicious use of plants specially adapted for basket-culture, of which there are both foliage and flowering plants enough to give ample variety. And as the object is to display the charms of the plant it is not necessary that the basket shall be any elaborate affair of rustic work, appropriate as these undoubtedly are for certain purposes, but a simple wire basket; such as the old-fashioned ox-muzzle, or those shaped like a basin will answer the purpose fully.

In filling these baskets it is necessary to line the frame with moss, to keep the soil in place; either live sphagnum or green flake moss from the woods is suitable material, and generally any ordinary potting soil will answer as a compost. Proper attention must be paid to the watering of basket-plants, for being exposed to the air on all sides, they naturally dry out rapidly when well established; it is advisable to give them a dip in a tub of water occasionally, in order to insure their thorough watering.

Begonia glaucophylla scandens deserves more general recognition for basket use. It is the finest of its family for this purpose, being handsome in foliage and almost always in flower. *B. glaucophylla scandens* is a strong-growing species. I have seen it with shoots fully three feet long, making a perfect screen around the basket. The tips of the shoots are well clothed with an abundance of coral-red buds and open flowers of a lighter shade. As with all *Begonias*, the propagation of this species is very easy; some shade is needed to secure a rapid growth.

An admirable group of basket-plants is also found in the *Æschynanthi*, and also a somewhat uncommon one, at least in our American collections, though grown in some commercial establishments of this country at least twenty years ago. The *Æschynanthi* form a part of the *Gesneraceæ*, and consist of a number of species of more or less scandent plants with small opposite leaves of fleshy texture; the flowers are formed at the tips of the shoots and from the axils of the leaves, and are tubular in shape and usually bright-colored. These plants require a warm house and plenty of light to make them flower freely, though a slight shade is beneficial in the summer in preventing scorching. A light rich soil is best, and should be very porous. The addition of some rough lumps of peat and pieces of charcoal give the best results, and during the winter a comparatively small quantity of water will be required. Among the best species are *Æschynanthus fulgens*, *Æ. Lobbianus*, *Æ. splendidus* and *Æ. pulcher*, the flowers of the first-named being crimson with an orange throat, while those of the other three are various shades of scarlet.

Episcia Chontalensis, perhaps more readily recognized under its older name of *Cyrtodiera Chontalensis*, is another useful member of the *Gesneraceæ* for basket-culture, and has slightly hairy leaves from two to three inches long, purplish on the under side and green above, the flowers being lilac, with a

white centre. This is a shade-loving plant, and needs no special attention if grown in a temperature of sixty degrees.

The *Torrenias*, also, are admirable plants for this purpose, *T. Asiatica* being the most scendent in habit, and producing its four-lobed flowers of purple and white in the utmost profusion, an abundance of water and plenty of light being the essential points of culture. During the summer months there

The Cultivation of Cattleyas.

LOOKING backward forty years, in the garden literature of that period, nothing is more striking, when we compare them with the periodicals of to-day, than the absence of Orchid notes. Collections of these plants were unknown outside of a few botanical gardens, and their cultivation was so

Fig. 96.—New Chrysanthemum, Golden Wedding, reduced one-third.—See page 556.

are few more showy objects in the conservatory than some well-filled baskets of *Achimenes*, the tubers of which should be started beforehand, and then planted around the sides of the basket. By this method a complete mass of foliage and bloom will ultimately be secured, providing warmth and moisture and some shade are given.

Holmesburg, Pa.

W. H. Taplin.

little understood that the plants rarely lived long. Now that we adopt a more rational system, the majority of plants can be made happy for a number of years, if not an indefinite period; for, while it is possible to grow *Cypripediums* for all time if their wants are supplied, the same is not true of some other genera and species, and cultivators well know how difficult it is to maintain in vigorous health some of the Cat-

tleyas, Dendrobiums, Phalænopsis and others. Rapid communication with the tropics has made the importation of Orchids much easier than ever before, and it is now possible to purchase, at a low price, within the reach of all, fresh imported plants that, with ordinary care, will start to grow at once, and should flower within the first year of their growth here. We have an admirable climate for the culture of Orchids in America, with a most suitable material at hand to grow them in, that is, the fibrous roots of the ubiquitous *Osmunda*.

The season of importing Orchids is now here, and a few remarks on treating *Cattleyas* may be useful to those who may wish to grow a few of the more popular kinds, such as *C. Trianae*, *C. Percivalliana* and *C. Mossiae*. All *Cattleyas* are kept dormant during transit here by lack of moisture, and the consequence is that directly the plants are received and placed in a genial atmosphere of 60 to 65 degrees, with moisture supplied by syringing once a day, they will commence to put forth roots in a very few days, and it is well to anticipate this by potting them as soon as ever they show signs of growth, using pots half-filled with crocks, just large enough to contain the bulbs, and the new ones that are about to be made the coming year. If all goes well, the pots will be full of roots in a year and need more root-room, and this is preferable to the use of pots too large at the outset, for the plants will never thrive if over-potted, or if a quantity of organic matter be placed about the roots. Good Fern-root, combined with a little sphagnum, is the best material to use in potting. The sphagnum is not necessary to the plant's well-doing, but is an excellent index to the condition of the plant as to moisture and a reminder when to apply it. All Orchids should be potted firm in the beginning, and to make sure of this stakes should be used to secure the plants, that when they make roots they will not be broken or injured by oscillation. These stakes may be removed when roots are formed, as these soon attach themselves to the pots and keep the plant firm. A night temperature of 65 degrees will suit newly imported plants, but for those established 55 degrees will not be too low as a minimum. All plants of *Cattleyas* that have finished their growth for this season should be kept a little drier at the roots than when in active growth, though it is never advisable to keep *Cattleyas* quite dry for any long period, or the bulbs will shrivel and lose vigor and the flowering period will not be such a gay one.

Plants of the old *C. labiata* will now have passed flowering. This is one of the finest of all winter-flowering Orchids, being exceedingly vigorous, a free bloomer, with a large percentage of good varieties; but its chief merit is that of flowering at a period when so few other showy kinds are to be had in bloom. After flowering the plants should be kept quiet, for it must be remembered that this plant takes its rest after flowering instead of before, as in many other kinds. The most perplexing feature of newly established *Cattleyas* is the way they have of starting to grow in and out of season, or just when they please. I have often been puzzled to know what to do with plants that start into growth when the resting period is at hand. The cause seems to be excessive vigor, and after a season or two, under good treatment, the plants settle down to a regular succession of rest and growth, which is a most desirable condition of things.

All *Cattleyas* should have the full benefit of the sun at this time of year; the foliage will become well ripened by its influence, and less moisture in the atmosphere is required while the plants are at rest for the next three months. The time to repot *Cattleyas* varies with the variety or species. We have recently potted plants of *C. Jaskelliana* that had begun to root freely, as these do not flower until next summer, but the majority of kinds may safely be repotted soon after they begin to push forward young growth in spring. Many kinds are rooting freely now, but it would be unwise to disturb them just previous to their flowering.

E. O. Orpet.

Agapanthus umbellatus.—Two centuries have elapsed since this grand plant was first brought to Europe from the Cape of Good Hope, and in that time it has steadily made its way until it has become indispensable to every important floral establishment in the world. Commonly called the Blue African Lily, it is immensely popular with all classes of cultivators, the rich as well as the poor. It is a plant of elegant habit, with large fleshy roots, and deep green strap-shaped leaves, which are upward of two feet in length when fully developed. The slender scapes are erect, about three feet high, bearing large umbels of bright, sky-blue, spreading flowers, each an inch and a half in diameter. The flowers appear most profusely during late summer and in early autumn, but

the season may be prolonged even to the verge of winter by giving liquid manure about twice a week when the plants show signs of exhaustion.

There is no better plant for the piazza, and it may be safely wintered in a dry, frost-proof cellar. Rich, sandy soil—loam, well-decomposed cow-manure and sand in equal mixture—ample drainage and, in the growing season, plenty of water are the chief accessories to its successful cultivation. The plant may be dried off in winter, but it should not be disturbed at the root very often, unless it is desirable to increase the size of the specimen. Pot-bound plants flower most freely, and they are easily kept in luxuriant health by supplying fertilizers in liquid form. Its management is, of course, simplified where the grower has a greenhouse at disposal, and it will yield a greater amount of pleasure in such places, but no one needs to be deterred from adding it to his collections of dwelling-house plants, as a greenhouse is not at all necessary to its perfect well-being.

There are several varieties of *A. umbellatus* in cultivation. Of these may be mentioned *Albiflorus*, producing white flowers; *Maximus*, in every respect more robust than the type; and *Variiegatus*, with green and white foliage. All these are desirable and very decorative, but the old-fashioned species is perhaps more reliable than any of the others. It is readily propagated by division.

Thunbergia erecta.—This plant, formerly known under the generic name *Meyenia* (a genus now incorporated with *Thunbergia*), is one of our prettiest stove shrubs. It was introduced in 1856 from Africa, where it inhabits the region of Cape Coast Castle. The habit is graceful, though extremely bushy where the branches are occasionally pinched and pruned. These operations are, indeed, necessary for the production of a neat specimen, for the plant is naturally a loose, rambling grower. The ovate leaves are small, opposite, and of bright green color, the larger ones generally dentate. The flowers appear singly at the axils of the leaves, on short, slender peduncles. The curved tube is white, orange inside, and about an inch and a half long, the limb of five spreading segments two inches in diameter, and of a charming blue-purple color. The plant is scarcely ever out of bloom; but it flowers most freely during the winter months, being then densely covered with its rich-colored blossoms from top to bottom. It is unfortunate that the flowers are not fit for cutting, and even on the plant they last but a short time. This, however, is the one weakness of all the *Acanthaceæ*, the order to which the *Thunbergias* belong.

Good flowering specimens of *T. erecta* are soon obtained from cuttings of the young wood, for it is a rapid grower under favorable conditions. They may be quickly rooted in sand, with the aid of a little bottom-heat, at any time of the year. The plant likes a strong, moist heat, and a compost in which rich sandy loam predominates. *T. erecta alba* is a beautiful white-flowered variety—a plant quite as attractive and useful as the species, and requiring precisely the same treatment.

Clerodendron fallax.—This is a stove-shrub of bold appearance and exceedingly decorative. It belongs to the bushy section of the genus, as distinguished from the climbing species, and is a native of Java. It is of erect growth, and makes a shapely plant from three to four feet high. The branches are well furnished with large, opposite, cordate leaves, deep green in color, and the brilliant scarlet flowers are borne in dense terminal panicles from six to nine inches in diameter. All the parts of the flower, except the brownish tinted anthers at the top of the conspicuous curved stamens, are of the same bright color; the spreading corolla, divided into five oblong segments, is irregular in form, and almost two inches across. The flowering season begins in August and draws to a close about Thanksgiving. The plant should be cut down to within two or three joints of the previous year's wood immediately after the flowers have faded, and be kept rather dry in an intermediate temperature during the winter months. A little larger supply of water may be given in early spring until the shoots show signs of pushing forth; the plant may then be turned out of the pot, the greater portion of the old soil removed from about the roots, and repotted in a mixture of strong turfy loam, fibrous peat and thoroughly decayed cow-manure, in equal parts, with a little sand added. It should then be placed near the glass in a moist house, the temperature of which is never allowed to fall below sixty degrees, and encouraged to grow. Liquid manure should be given two or three times a week after the flower-buds appear. This will aid considerably in the formation of large panicles. The plant should be syringed frequently in summer to keep down the red spider, and shaded

during bright sunny weather. It is easily multiplied by removing some of the short young growths, with a small portion of the older wood, in early spring, inserting them in the sand of a propagating-bench and shading until rooted, when they may be managed in the same way as older specimens. Young plants grown in this manner will flower during the ensuing autumn if confined to a single stem. Seeds of *C. fallax* are sometimes obtainable, and good flowering plants may be had from them in two years. They should be sown in spring, using sandy soil, and placed in strong heat until the plants appear. Pot them off singly when large enough to be handled without much trouble, and treat them afterward like plants raised from cuttings, pruning the stem to a couple of nodes above the soil in winter.

Cambridge, Mass.

M. Barker.

Begonia decora.—This is a new species of *Begonia*, and one which is likely to become a favorite in gardens because of its prettily marked leaves. It was found in Perak by Mr. C. Curtis, who sent it to Messrs. J. Veitch & Sons, Chelsea, by whom it was exhibited at the *Begonia* Conference last August under the name of *B. barbata*. This latter name, however, belongs to a well-known and common Burmese species, of which plants have been in cultivation at Kew since 1886, when seeds of it were sent home by Mr. C. B. Clarke, F.R.S. *B. decora* has a short fleshy stem crowded with leaves, the petioles of which are four inches long, and the blades obliquely ovate-serrate, not lobed, and five inches long by three inches in width. The whole plant is covered with a soft pubescence, giving it a velvety feeling, and the leaf-blades are colored a bright coppery red, with conspicuous veins of yellow-green. The flowers are pink. The plant appears to require stove treatment.

Correspondence.

California Oranges and Lemons.

To the Editor of GARDEN AND FOREST:

Sir,—I have been spending the first week of November among the orange and lemon growers of southern California, and I am greatly interested in the more recent features of Citrus culture. Without instituting any odious comparisons with Florida, the only rival Orange state, I cannot help feeling that the well-directed energy and intelligence of the horticulturists in the colonies I have been visiting can hardly be surpassed in any other part of America. I look upon Riverside, Redlands and the San Bernardino country generally as fairly typical of the most advanced Orange treatment in California; nearer the coast, at Santa Paula, Ventura County, the culture of the Lemon is as well understood as anywhere else in the state. Everywhere in the great Citrus fruit districts that I have studied a far higher ideal prevails now than ten years ago; the fascinating industry is becoming permanently established by highly educated specialists who love their work.

Twenty years ago there was no one in California who really knew much about Citrus fruits. A few families of small means founding colonies, under great difficulties—social, legal and physical—obtained water for irrigation and began experiments. When their efforts had fairly created a new industry the inevitable era of land-speculation set in, and dotted many a rich valley with mushroom towns. Thousands of promising young Orange-groves were neglected; progressive horticulture received a check; the weeds often grew waist-high in orchards where the land-boomer had driven his town-lot stakes. As this craze died out, the solid towns grew faster than before, and the tide of investment flowed back upon horticulture. The last five or six years have witnessed a marvelous development, especially in the Citrus fruits, which appear to belong more and more to certain districts, and to be more and more the specialty of certain families and colonies.

The true limits of successful Orange culture, long loudly quarreled over, are being settled by the simple commercial test—the sale of products in the open market. Details of culture—problems of stock, planting, pruning, and all that—are discussed daily, and almost hourly, in the Orange districts. Active organizations, with committees in every department, watch the whole world for news about orange matters, and are prepared to act as a unit. Every new variety is tested; all that skill and money can do to raise the standard of the product is constantly being done in such districts as Riverside.

Observe, for instance, the present behavior of Riverside respecting the frost question. The valley has about 50,000 acres under irrigation pipes and ditches. The annual planting of Citrus fruits is between 3,000 and 4,000 acres. Some winters

the temperature falls so low that the oranges are injured or destroyed. The meteorological record shows that the minimum temperature during the past ten years at the town of Riverside has once fallen to twenty-one degrees, once to twenty-five degrees and twice to twenty-six degrees. The lowest was ruinous to much of the fruit, and the others injured fruit in some orchards. The sensible Riverside horticulturists, instead of denying all this, are facing it, confident in their own ability to conquer the difficulty; they are using appliances for warming the orchards on a large scale. Their experiments show that the temperature can be raised from four to ten degrees by the use of fires. The moment that the thermometer falls to the danger point electric-bells can be rung and tanks of crude California petroleum can be lit. One gentleman has fitted up an eighty-acre orchard at a cost of \$10,000 or \$12,000. He claims that his grove is now absolutely protected, and that the running expense will be very little. Since his crop is worth \$50,000, and since a single night such as the freeze of 1891 would destroy every orange, the wisdom of the system is manifest. Other growers use coal-oil cans, filled with kindling-wood and coal, and placed in the orchard at the rate of from eight to twenty-five per acre. Some provide themselves with two-gallon iron kettles, and use reduced petroleum, costing in Riverside about ten cents a gallon. Ten dollars per acre will pay for the plant and the expense of one night's burning. Progressive horticulturists in other Citrus colonies are following in the track of Riverside, and preparing for future "cold snaps."

Thousands of writers have described in magazines and books the beauty of the more famous Orange colonies. While the stranger feels this first, there is, I notice, a broader and more fundamental fact about such places as Riverside. The whole community throbs with one purpose. The most wisely directed horticultural skill is continually at work bringing forth, through vast toils, new achievements. Each new tract planted requires in some degree special treatment, according to slope of hill, currents of wind, altitude or variations of soil. What fine hereditary knowledge of their art the orange-growing grandchildren of these Riverside pioneers may hope to possess!

The Lemon, long scorned in California, begins to receive much attention. N. W. Blanchard, of Santa Paula, grows the Eureka, the Lisbon and the Genoa. He has a large sweat-house, and produces a lemon that compares very favorably with the best imported. He cannot supply the San Francisco demand, and is planting 400 acres more. The trees are allowed to trail their lower branches on the ground, and seem far more picturesque in growth than Orange-trees. The fruit is cut when at the desired size, and while still green, so that one seldom sees a yellow lemon in the entire grove. In the older Orange colonies of southern California the Lemon is rapidly rising in favor, and large orchards will be planted the coming season. Villa Franca, Sicily and Lisbon are the varieties generally chosen. The best Sicily lemon is the Royal Messina, a recent introduction.

Berkeley, Cal.

Charles Howard Shinn.

Pedigree Seedling Chrysanthemums.

To the Editor of GARDEN AND FOREST:

Sir,—I am not altogether satisfied with the results of my experiments in raising pedigree seedling Chrysanthemums. I started three years ago with the settled conviction that John Thorpe was right. I have watched every little detail. I noted all the first seeds to germinate, and found, contrary to the general idea, that there was as great, if not a greater, percentage of good double flowers among them than those germinating later. Against the recommendation to discard weak seedlings, I have saved some for testing, and the majority gained vigor and produced a good percentage of fine flowers. When pollenizing, I found that full double flowers had a greater percentage of trifurcate stigmas than flowers in which the disk florets predominated; that the seedlings from these flowers were mostly tricotyledonous, and what is still more important, that all these seedlings produced full double flowers. Ligulate florets produced seedlings which maintained in a marked degree the characters of their parents, however much they diverged in color. V. H. Halleck was not influenced by any other color-cross than yellow, and all seedlings from it were either flesh-pink or yellow. On the contrary, it impressed itself upon all others. I have observed a tendency to earliness in all varieties; early varieties produce yet earlier seedlings, even when crossed by late varieties, and taking their character in other respects. For instance, E. Molyneux, early crimson, crossed with Walter Hunnewell, late orange, gave all early seedlings and mostly yellow. Goldfinder, late yellow, × L. Boehmer, early

pink, gave an early pink-flowered variety, with Goldfinder's peculiar character of flower. Violet Rose dominated all it came in contact with, but produced no seedlings itself of any distinct value. It was not always the strongest variety which made the greatest impression. Mrs. Alpheus Hardy showed its influence upon all it came in contact with—some very distinct varieties producing pure white spiny flowers. The pure incurved Chinese completely dominated the Japanese. Louis Boehmer \times Belle Pointevine, white, gave a first-rate white incurved flower; and by a yellow incurved, various shades of yellow and bronze, all incurved, and very few spiny. The incurved forms, on the contrary, showed no trace of Japanese influence, all coming perfectly and truly incurved. The whites varied to yellow, and yellows to white.

It has been suggested that better results might be had by emasculating the fertile florets of the disk, pollenizing only the ligulate florets. In my experience, seeds from the ligulate florets are not produced in the proportion of more than one seed to one flower, or, botanically, one head of flowers. A further, and more reasonable, suggestion is to take the fertile florets found scattered through the ligulate ones, even in the most double flower, as being less liable to insect agency than an open disk.

The deductions are, that while artificial crossing may, and often does, give the result looked for, we have not yet established any laws which we can trust with any degree of certainty.

Wellesley, Mass.

T. D. H.

New Cypripediums.

To the Editor of GARDEN AND FOREST:

Sir,—Cypripedium \times Ephialtes is the name proposed for a cross between *C. insigne* Chantinii and *C. aureum*. It is compact in habit; the foliage is sparsely mottled with deep green on a pale ground, silvery underneath; the single flower is produced on a brown pubescent scape; the dorsal sepal is orbicular, pubescent on the back, front smooth, very pale green, bordered with white and carmine, with the radiate veins bright green, the principal ones spotted with brown; inferior sepal veined with pale green, petals pointed, margined with black hairs, rich brown, veined and shaded with green, with an occasional dark brown spot on the surface and margin, lip acute, brown on front, pale green beneath, with darker veins, infolded lobes dull waxy yellow, speckled with brown, staminode green and brown.

Cypripedium \times luridum, var. grandiflorum, is the largest of the Harrisianum section, and one of Pitcher & Manda's hybrids between that species and *C. aureum*. The foliage is bold and striking, scape pubescent, flower waxy, dorsal sepal twisted, veined with dark green, and shaded with brown on a white ground; petals minutely pubescent on margins, rich brown with green nerves, and a median line of dull purple; lip dull green-yellow, faced and veined with brown.

Cypripedium \times Cybele. This beautiful hybrid is the result of a cross between *C. Drurii* and *C. Lawrenceanum*. The foliage is glossy, compact, six inches long by two wide, light pea-green with deep green neuration; scape and seed-pod brown, very pubescent; flower much the shape of *Drurii*; dorsal sepal flat, slightly incurved, villous on the back and margin, white, shaded and reticulate veined with pale green and vinous brown, with a deep brown midvein; inferior sepal white, with striate green veins; petals somewhat incurved, with apices reflexed, pilose on the margins, brown, shaded with green, with a median vein of rich vinous purple, spotted near the base with brown; lip symmetrical, rich waxy brown, paler beneath, pubescent and speckled with purple inside; staminode broadly obcordate, vinous purple, with a pale green spot in centre. This plant is one of the most conspicuous of the genus. It was raised by Pitcher & Manda.

All three of the above plants are now in bloom in the collection of Mr. Graves, of Orange, New Jersey.

Orange, N. J.

Robert M. Grey.

Snow Scenes.

To the Editor of GARDEN AND FOREST:

Sir,—This morning everything was covered with a mantle of soft snow, like that more often seen in late winter or early spring. The impressions, always so pleasing, which such a scene gives, were in this case heightened by the fact that some trees and shrubs have not yet lost all their foliage, and the effects produced by the different manner in which the snow was held were especially pleasing. An Apple-tree, for example, still bearing a few leaves, had the outlines of its crowded angular twigs brought out with particular distinct-

ness. Near by is a bank of natural forest-growth, largely composed of tall evergreens, among which an occasional deciduous tree reached out its bare arms, now conspicuous with their covering of white. On the street a group of Birches still held most of their foliage, and the faded color of the leaves, inseparably mingled with the minute patches of white, produced a curious, if not wholly artistic, effect. The Hemlocks and Pines stood out in strong contrast, one with its broad and heavy masses of white, the other with its more broken and varied outline, or in older and more thinly leaved specimens, with the needle-like leaflets still upright, and holding their beautiful load like a broken mass of foam.

These varying effects all emphasize the value of mixed groups in planting, and also the advisability of considering the character of different trees and shrubs in respect to this phase of their winter aspects. These lessons come but seldom, yet to most of us they pass unheeded. Even this is written from memory, as the scene is recalled. No doubt I could have found many specially beautiful effects to note if my attention had been fully aroused this morning, but now they are gone and I can only regret that, having eyes, I saw not until it was too late.

Cornell University.

Exhibitions.

The Cincinnati Chrysanthemum Show.

A MOST delightful exhibition opened in this city on November 8th, and continued throughout the week. Music Hall, one of the grandest auditoriums in the west, was tastefully decorated for the display of cut flowers, which were arranged on large tables nicely draped in yellow, the predominant color, and which made a pleasant setting for the tall crystal vases, which were large and heavy enough to display to their very best advantage the truly regal specimen blooms sent in by the numerous exhibitors, who had been attracted by an unusually liberal premium list.

One of the most attractive entries in the show was that calling for three blooms each of fifty distinct varieties. Nine tables of 150 blooms each competed in this class, constituting a whole exhibition in itself, and so uniformly good were these entries that the judges, Mr. John Thorpe and Mr. E. A. Wood, had considerable difficulty in forming their decision. Mrs. F. T. McFadden was awarded first premium, \$150; E. G. Hill & Co. came a close second, and Frederick Dorner a very close third. The number of varieties of recent origin was most noticeable, and we specially noted the following recent novelties, all in fine form, as weak stems and poor foliage were debarred from premiums: Edward Hatch, Harry Balsley, Mrs. Governor Fifer, George W. Childs, Colonel Smith, J. H. Taylor, Elmer D. Smith, Mermaid, Roslyn, Harry May, Sugar Loaf, Eda Prass, C. B. Whitnall, Golden Gate, Dr. Callendreau, Madame Forgeot, Marguerite Jeffords, Hicks Arnold, Mrs. L. C. Madeira, Potter Palmer, Viviani Morel, Mrs. Drexel, Flora Hill, Jos. H. White, besides many others from the recent sets. Harry Balsley attracted much attention, its color being similar to that of V. H. Hallock, and Marguerite Jeffords, as shown by Dorner, was one of the finest flowers in the hall, regular and very compact, and of fine size and color.

Of almost equal interest with the above was the class calling for best fifteen varieties, three flowers of each. This was won by George R. Gause & Co., Richmond, Indiana, and was generally thought to contain the most uniformly excellent flowers in the show. The fifteen varieties were: V. H. Hallock, Marguerite Jeffords, Mrs. A. J. Drexel, Mrs. L. C. Madeira, S. W. Allerton, Frank Thomson, Colonel Smith, L. Canning, C. H. McCormick, Edw. Hatch, Mademoiselle C. Krieger, Golden Gate, M. Wanamaker, Harry Widener.

The prize for twelve best pink blooms was won by Viviani Morel; twelve best white, by Ivory; twelve best yellow, by H. E. Widener; twelve best of any color, by E. G. Hill; and a vase of twelve Mermaids, shown by George Gause, was so fine as to call for a special award of merit.

As usual, very great interest centred in the seedlings; the award for the best one never exhibited previous to 1892 was won by Nathan Smith & Son with Niveus, a very fine white variety of immense size, a perfect ball of straight erect petals, the foliage showing it to be a fine grower. For second best seedling not previously exhibited, the award was made to Henry Rieman, of Indianapolis, for Irma, a small, perfectly incurving Chinese, of violet-pink color. This won enthusiastic commendation from both judges, but, as usual, the Chinese regularity failed to please the public at large, as do the more imposing Japanese forms.

The Storer prize for best white seedling was won by Frederick Walz, with *The Queen*; this also won the premium for best white at Madison Square last week, and is a most beautiful novelty. The Schindlapp prize was awarded to E. G. Hill & Co. for best pink, named *A. T. Ewing*, a broad ribbon petaled variety of great substance, the color arranged in bands on creamy white. The Hinkle prize was won by the same firm for best crimson variety, Mrs. J. W. Crouch, a large incurving sort, with broad petals of purplish crimson.

E. G. Hill & Co. also won the Florists' prize, with Robert McInnes, an immense, perfectly double Wheeler of the brightest red and gold. These two also won first in their respective classes last week at New York.

The Longworth prize, best yellow, was won by Harry Sunderbruch, raised by Frederick Walz. This variety appeared elsewhere also in beautiful bush form, showing it a good sort for pots as well as specimen blooms.

National Society certificates were also awarded to Peter Henderson & Co. for their Golden Wedding, winner of the GARDEN AND FOREST cup, the Cutting cup and another capital prize at Madison Square. To Frederick Dorner, for Mrs. C. H. Duhme, a feathery white of the greatest beauty; for Autumn Queen, a fine globular yellow; for Sarah Hill, a golden yellow of great substance. E. G. Hill & Co. received certificates for Mayme Ryar, a Japanese Anemone; Robert McInnes, the double Wheeler, which recently received first prize at Madison Square; for Judge Hoitt, an enormous pink Anemone, and Maud Dean, a rosy pink, very large and of flat incurving form. Mr. Walz received certificates for Theodore Bock, a lovely rounded pink, Vesuvius, a beautiful amber-yellow with touches of reddish brown, and also for the prize-winner among whites—his beautiful White Queen. Several other seedlings of great merit were passed by this year which certainly will be heard from again. Every entry made in this class was of great merit, and the table was most remarkable as containing not one freak or curiosity—form, fullness, size, color, stem, foliage being finely exemplified in each case.

The pot-plants were arranged with effective taste in Horticultural Hall, which is reached from Music Hall by a covered corridor. Winding walks were bordered by bands of Crowfoot and Laurel tacked to the floor, and enclosed the various exhibits. The general effect was that of a garden in full bloom, the centre-piece, a grand pyramid of Palms, very restful to the eyes. A most instructive class was the eighteen market-plants, which were a good object-lesson, and a necessary one, to many a florist present; one group averaged about two feet in height, and carried from sixty to seventy perfect blooms of medium size; most notably beautiful were Ivory, L. Canning, M. Boyer, W. H. Lincoln, Puritan, Ada Spaulding, Princess Beatrice and E. G. Hill. In another entry for this premium were George W. Childs, Mrs. Craig, Hicks Arnold and Minnie Wanamaker, all in extra good form.

For the best collection of twelve plants in twelve varieties the winning exhibit contained Miss M. Wheeler, E. G. Hill, T. C. Price, G. F. Moseman, Mrs. Humphrey, Mrs. Fottler, Domination, Kioto, Grandiflorum, Ada Spaulding, Delie and Rosebank. There seems to be an increasing interest in well-grown pot-plants, and many florists were busy with note-book and pencil among the finest specimens. For five finest whites in bush form the winning plants were Domination, R. Bottomly, M. Wanamaker, Mrs. Humphrey and L. Canning. The finest specimen white in the show was Minnie Wanamaker, and this noble variety again won admiration in the best fifty plants, one variety, grown to a single flower, but was closely followed with fifty specimens of Ivory grown in the same style.

There were five entries in the class calling for 100 plants, not more than four of a kind, grown to a single flower in seven-inch pots. Here, again, the competition was very close. The sorts which at once caught the eye were Princess of Chrysanthemums, Harry Widener, Kioto, Baronald, V. Morel, F. Thomson, Eda Prass, R. Maitre, Mrs. Langtry, International, L. B. Bird, Mrs. Simpson and C. H. McCormick.

Four magnificent groups of Cannas, composed of fifty plants or clumps each, made a blaze of color against the dark gray wall. The McFadden group was almost exclusively Madame Crozy; E. G. Hill's group contained some ten of the latest Crozy novelties; very conspicuous were J. D. Cabos, A. Bouvier, H. A. Dreer, Miss Sarah Hill, F. Thomayer, Capitaine Suzzoni, Duchess Mortemarte and Nardy Pere. These won the very liberal premium of \$150, the McFadden group taking second. The other two groups had been injured in transit; but a point to note on Canna exhibits is that the blooms improve each day of the show, as the buds unfold and replace the fragile beauties, which are always injured more or less, despite the most careful packing.

Roses and Carnations, which reign eleven months in the year, were shown in grand style on Wednesday. American Beauty was in especially fine form, grand bunches on long stems forming a centre for each exhibit. American Belle, the new sport, was also shown in fine condition, and was most critically examined by every florist present. Nanz & Neuner showed white La France in great perfection. Madame Caroline Testout arrived too late to enter the lists, but was constantly the centre of an admiring crowd.

The grand surprise of the show, however, came when Mr. Peter Herbe, of Mount Healthy, set up his Carnations. He showed several seedlings of immense size, one of the Anna Webb type fully three inches across; a second of reddish pink fully as large and of magnificent build, which was awarded first premium. These two seedlings are most remarkable, notwithstanding the fact that one shows a rather weak calyx, and the other a slender stem. They mark a distinct departure in this exquisite family. Mr. Dorner's seedlings were out in lovely array, with bright clear colors and good stiff stems, and they made a beautiful display of some ten fine novelties. Mr. Witterstaetter showed Daybreak in absolute perfection, its only rival being Edna Craig, which stood up bright and crisp as crystal.

We cannot close without a passing word for the display of Ferns and Palms. Finer examples of the Adiantums are seldom seen than those in the Huntsman collection, some of them nearly three feet across. Extraordinary specimens of *Pteris argyrea* were seen, and Critchell made a grand display of neat medium-sized plants in some forty varieties, which proved a most interesting study for the lover of this beautiful family. There were three grand displays of Palms beside the centre-piece. *Areca lutescens*, *A. Verschaffelti*, *Chamærops filamentosa* and a *Phoenix rupicola* were magnificent.

The two tables of Cyclamens by Mrs. McFadden and Julius Peterson were surrounded constantly by admiring crowds. Every plant was in great perfection both as to foliage and bloom, and the effect was only second in point of beauty to the singularly rich and rare Orchid display made by John Rose, of Rosebank.

Recent Publications.

Field-Farings. By Martha McCulloch Williams. Harper & Brothers.

This neatly bound and printed book adds another to the numerous "nature studies" which have become such a prevalent modern fashion. In thirty-two separate sketches we find sympathetic descriptions of many varied phases of earth and sky. Beginning with "Snowfall," and ending with "Come Christmas Day," this out-of-door calendar of the year records pleasant and profitable rambles by tinkling brooks and through green meadows, and quiet walks in brown fields and deep woodlands. There is no attempt to discuss scientific questions or to draw profound moral lessons, but a "Vagrant Chronicle of Earth and Sky," the not altogether unaffected sub-title of the book, reveals a habit of close observation and of delightful familiarity and friendship with nature, animate and inanimate. The keen enjoyment of country life under the open sky is shared by the reader, for the descriptions have an evident basis of real experience which is at once satisfying to the lover of nature, and impressive and inviting to such as are content with a merely passive enjoyment through wanderings by book.

The chapter on "New Ground" shows an appreciative understanding of the forests, and suggests an attractive field of study for women. The gaining of new ground for the husbandman by the woodsman is vividly described, and a practical knowledge of the quality and uses of timber of various trees is shown. Foxes, minks, weasels, wood-ducks, wild turkeys and other inhabitants of water and woodland are described in their favorite haunts and at various times and seasons. To the restful, quiet walks, in which the reader takes part, is added the excitement of a fox chase in the chapter "In at the Death," and the hunter, teamster, farmer, woodsman and fisherman all play their part in these picturesque sketches. The latitude of West Virginia is suggested in descriptions of a land of snow in winter, of planting-time in March and April, and of Walnut, Hickory, Tulip, Sycamore and Magnolia trees, and orioles, humming-birds, 'possums and 'coons.

The chief charm of the book is not, however, in its account of the song of birds, the patter of summer rain or the silent caress of enfolding snow, nor in the happy sketching of the habits of wild plants and animals. Its deeper merit consists in an insight into the poetical and practical significance of

many commonplace things which seldom receive attention, or, at most, only passing notice as a general part of the landscape.

These glimpses at nature are not a little marred by an affectation of archaic and unusual words and phrases. The very first sentence opens unpromisingly with "An you love nature," and this is followed by "awreath," "arustle," "ahuddle," "aperch," and many more disagreeable words. This blemish of artificiality is so evident that it inspires the reader at first with distrust of the genuineness of the descriptions and comments, and it requires some patient effort to find out the worth of the book. *Field-Farings* is best read in snatches, and a chapter indoors in winter has something of the pleasant refreshment of a summer ramble across fields and in shady woodlands.

Notes.

It is a matter of surprise that the Cape Heaths are not grown more frequently than they are. Twenty pots of *Erica Wilmoreana*, all evenly grown and well furnished with delicate pink flowers, were shown at Madison Square Garden by Louis Dupuy, of Whitestone, Long Island, and were universally admired.

The National Chrysanthemum Society, of London, have issued a supplement to the customary edition of their official catalogue. It contains a carefully revised list with short descriptions of all varieties introduced since the publication of the list of two years ago. This is the standard publication for Chrysanthemum names, and of interest to all growers of these flowers.

The Chrysanthemum which was exhibited at the Philadelphia exhibition a fortnight ago, and for which its originator, Mr. David Cliffe, received first prize as the best pink flower, has since been named Magnet. The color is described as a cameo-pink, with the inner part of the petals rather deeper in shade. It is an incurved flower, very double, full, and shows no centre. It keeps unusually well, is a flower of the largest size, and has a strong habit and good foliage.

A horticultural journal published in Ghent says that the indoor cultivation of the Castor-oil plant has been recommended as a protection against the summer plague of flies. "We are told," says the writer, "that if a single small plant is placed in a room, all the flies the room contains will soon be found glued to its leaves, or, assassinated by its juices, strewing the floor in its vicinity. We do not vouch for the truth of this statement, but so simple and cheap an experiment is certainly worth trying."

Changes have recently been made in the plans for the monument to Alphand, the famous landscape-architect, which, immediately after his death, it was decided to erect in Paris. Instead of Monsieur Formigé, the architect first selected to design the monument, it will be designed by Dalou, one of the two or three greatest sculptors in France. It will stand in the square called St. Jacques-la-Boucherie, which surrounds the famous Gothic tower of St. Jacques, which was laid out by Alphand himself.

A correspondent of *The Tribune*, speaking of certain peculiarities of California, states that tropical fruit may be grown in the foot-hill belt along the base of the Sierra Nevada Mountains as far north as the parallel of Springfield, Illinois. Some of the finest Oranges in the state are grown at Oroville, in Butte County, and the Orange-groves are irrigated by old mining ditches. Near Auburn, in Placer County, a rancher has fine Banana-trees which produce fruit, and they have no other shelter than a stout hedge.

In addition to the plants named in another column of this issue as suitable for baskets, *Cissus discolor* should not be forgotten; its richly variegated foliage is specially attractive when pendent from a basket. Another point in favor of this plant is that it is so easily grown and propagated. *Panicum variegatum*, old and common as it is, is a useful plant, and as any small shoot of this grass may be planted with the full assurance that it will root, there is no difficulty in keeping up a stock of it or making up a flourishing and attractive basket at short notice.

A correspondent of the *Monthly Bulletin*, of the Horticultural Society of Mons, writing recently of the American Red Oak and of the comparisons so often drawn between it and the indigenous Oak of Europe, says that he recently examined trees of both these species growing in a private park in the

neighborhood of Mons. The Red Oaks, at one metre from the ground, showed an average circumference of one metre five centimetres, while the common European Oaks (*Quercus robur*, var. *sessiliflora*), which stood near by and had been planted in the same year, gave an average of only seventy centimetres.

The many parks of Berlin, according to a correspondent of the *Evening Post*, "are almost entirely cared for by women—old women—who wear large black straw hats, sloping down from the crown in all directions, and blue jean aprons. The grass is never raked, but swept with large brooms made of birch-twigs, and the old women go all over it and the gravel walks, keeping both as neat and trim as possible. In the Thiergarten all the fallen leaves and twigs and fagots are promptly gathered, and one never sees even the remotest corner any other way than exquisitely well kept."

An illustrated monthly paper, called *The Whole Family*, which has just been started in Boston, will for some time to come devote an article in each issue to "The Parks and Pleasure-grounds of America." In the first number Boston Common was described, and its history—of course, the most interesting history of any of our public pleasure-grounds—was recounted; in the current number we are told about Druid Park, in Baltimore, which, perhaps, is more natural-looking than any other of equal extent that we possess; and both the articles are accompanied by good reproductions of well-chosen photographs.

Many species of Mesembryanthemums, natives of Africa, the Canary Islands, Australia and other southern regions, are well known in American gardens. But in the south of Europe they are much more extensively employed, and a number of them are almost naturalized, especially in the south-western parts of France. It is interesting to read in a recent issue of *Le Jardin* that at least one species, *M. crystallinum*, our familiar Ice-plant, supposed to be a native of the Cape of Good Hope, grows there sub-spontaneously, especially in chalky regions, and has been recommended as an article of food. It is to be prepared, we are told, in the same manner as spinach.

According to the *Southern Lumberman* it is an admitted fact that Poplar-timber is practically exhausted. Of course, there are tracts where a great many of these trees are still found, but each season will bring fewer logs and of lower quality, so that the lumbermen are looking out for the best substitute. Cotton-wood seems to be the only resource, and the eyes of the lumbermen are now on the delta lands of the Mississippi and its lower tributaries, where there are vast forests of this timber, soft, straight-grained, easily worked, that will answer as a substitute for Tulip Poplar, both for inside and outside use. The timber holds paint well, and when it is kept painted it is quite durable.

Some years ago artificially colored flowers, as ugly as they were ingenious, appeared in our shop-windows. The vogue they enjoyed was very short, for in a few weeks not a specimen could be found. Last year similar flowers became quite fashionable in London; and now, we regret to say, they have reappeared in New York. Even the great bunches of Carnations, colored a sickly bluish green, which the window of a florist on Broadway displays, are not quite so offensive as the Chrysanthemums, similar in color, which the street-venders on Twenty-third Street offer. The former look like impossibly ugly real Carnations, but the latter look like paper-flowers manufactured by some artisan with uncommonly bad taste.

The most valuable product of the Eucalyptus-trees which are planted in California are the essential oil and certain medicinal preparations from the leaves. The distilled extract from Eucalyptus, which resembles in its method of production the well-known distilled extract of Witch Hazel, has come into prominence within a few years. It is a concentrated extract from freshly gathered leaves of trees that are at least seven years old, and the older the better. It is used for most of the ailments where the oil has been used, and has the advantage of being cheaper. It has been recommended for headaches, nervous affections, and as an antiseptic it has given good results when applied to fresh wounds, and for inflammation of the mucous membranes and insomnia; for cold in the head and sore throat it is of service, while as a disinfectant it is useful from the fact that, like the oil, it substitutes a pleasant odor for noxious ones. The oil has an established place in the materia medica, and there is evidently a field of usefulness for the distilled antiseptic.

Specialized Horticulture.

THE request for certain information about Irises, which a correspondent makes in another column, suggests a subject to which we have before alluded, and that is, the instruction and recreation which can be derived from the careful cultivation of a single class of plants. Irises constitute a varied and extensive genus of perennial plants, and they rank among the most beautiful of garden-plants. They range in size from that of the towering *Iris (Moræa) Robinsoniana*, which has been figured in our columns, to the delicate little species like our own Crested Iris, which nestle close to the ground. Some of them are of the easiest cultivation, like the hybrids known as German Irises, and others like some of the *Oncocyclus* group are perverse, or, at least, wayward in cultivation, and require sympathetic care and the highest skill. Irises have always been favorites of those who devote themselves to the cultivation of herbaceous perennials, and yet there is enough to learn about the genus to fill the leisure hours of any one for years to come. Occasionally there is an enthusiast like Professor Michael Foster, of Cambridge, England, who keeps on the alert for every novelty of the family, and who tests each new one in his garden, but the flowers, in spite of their beauty, have never had any vogue like *Chrysanthemums* or *Dahlias*, and no Iris society has yet been formed, to our knowledge. So far as we know, there are not many large collections in this country, although one of our correspondents, Mr. J. N. Gerard, has cultivated about one hundred and twenty-five species and many more garden varieties.

Few occupations are more fascinating than specialized gardening of this sort. It is easy enough to get a general idea of any class of plants, but the farther we descend to particulars the more there is to study and to admire. If we care for garden decoration simply, we select for our purpose such plants as can be used with the most marked decorative effect; but as soon as we begin to have a special

interest in one class of plants we are drawn to them as to personal friends by an entirely different kind of attraction. We are eager to know all about their relatives and the habits of the family, and we are ready to study and explore every field from which any knowledge of our favorites can be gained. One can soon learn to grow, for example, all the species and varieties of *Iris* which make a show in the garden, but if he aims to be an expert in the cultivation of Irises, or to possess himself of authoritative knowledge concerning them, if to his admiration of their beauty and his affection for the special genus he adds the enthusiasm of a collector, he will have not only a diversion that will occupy all his leisure moments, but one that will also absorb as large a fraction of his surplus revenue as he chooses to appropriate for the purpose.

The enthusiast is cheered and sustained in all his labors and studies by the hope of securing a plant he has never seen, or of inducing one to flower with which he has often failed; and yet the results of his thought and care extend far beyond his personal gratification. The men who make a special study of a single class of flowers are the ones who really add the most to the general knowledge of plants. There is enough in many single genera of plants to occupy the leisure of a lifetime, and the plants only yield up their secrets to those who give them patient and affectionate study year after year. We have mentioned Irises, but, of course, there are many other genera which have their ardent devotees—enthusiasts who have their reward in the daily delight of increasing knowledge, but who also enlarge and enrich the art of horticulture by their experience. Daffodils, in their unending variety, have long been favorites of specialists in Europe, although large collections of them are rare in this country. Lilies appeal to a still larger class. The Saxifrage, hardly known in gardens conducted on conventional lines, has already become a pet flower of the specialist, and a list of the different species which can be furnished to buyers will occupy several pages in a catalogue like that of Monsieur Correvon, of Geneva. The various articles which we have published from the pen of Mr. W. E. Endicott show how wide is the range of knowledge and experience he has gained while recreating himself with the cultivation of the beautiful Cape bulbs, and his instructive writings on the subject are admirable examples of the extent to which the horticultural world is at last indebted to these special students.

When we begin with the greenhouse there is no end to the attractive families which invite special investigation. But if we undertake any branch of specialized horticulture, one of the first things we learn is not to attempt too much. We do not need to abandon all interest in general horticulture, for very likely a special devotion to one class of plants will give us an increased pleasure in all others. But the field of our systematic operations must be limited, and we shall be surprised to find that however we restrict its boundaries we shall still have too much for the careful study and experiment we feel inclined to give. This is the rule, and in this way has horticulture ever received its strongest impulse. In this direction too, lie some of the purest delights of the garden; in fact, there is no other way in which so much satisfaction can be derived from the cultivation of plants.

It is gratifying to observe that the movement to preserve the forests of the White Mountains, of which we gave an account some weeks ago, is meeting with very general endorsement by the papers of New England and the middle states, and that a fund has been started by the Boston *Herald* to aid this campaign of education. There is no need of any additional argument to show that the loss of these New Hampshire forests would be in the nature of a national calamity, or to prove that such a danger is constantly threatening so long as these forests remain in private hands and under our present laws. It is not an easy problem to decide just how this danger may be averted with the least friction to private interests and established customs, but

certainly nothing but good can come of such discussions as those now carried on by Mr. Harrison in every part of the state of New Hampshire where an audience can be gathered. Of one thing we may be assured, and that is that no effective action will be taken by the men who are chosen by the people of New Hampshire to make their laws until the people themselves are thoroughly educated to comprehend and appreciate the paramount importance of these forests to their general prosperity.

As is well known, the vineyards of California, especially those in the southern part of the state, have suffered severely from a disease first recognized by the appearance of discolored spots on the leaves. In some localities it is known as the Black Measles, and the damage to the crop has been very considerable. A number of persons have attempted to discover the cause of the disease, but hitherto no one has succeeded in detecting the fungus, if it be a fungus, which causes the trouble. Recently Messrs. Viala and Sauvageau have published the results of their investigations at the Ecole de Viticulture, in Montpellier, France. They recognize two diseases very similar in the effects they produce, one found in Europe and the southern United States, the other only in California. The former was first noticed in France in 1882, and is called *La Brunissure*; the latter, called by Viala and Sauvageau *Maladie de Californie*, is decidedly the more destructive of the two diseases. Both diseases are caused by species of *Plasmodiophora*, a genus of *Myxomycetes*, to which belongs the fungus which produces the so-called club-foot of cabbages. The fungi of this group consist merely of masses of protoplasm without the definite mycelial filaments of other fungi. The fungus of *La Brunissure* is called by Viala and Sauvageau *Plasmodiophora vitis*, and that of the *Maladie de Californie*, *P. Californica*. In neither species were they able to detect spores. The plasmodium of both species is found in the green cells of the leaves, especially in the large palisade cells, which are found just beneath the epidermis of the upper side of the leaves, and it varies greatly in shape and amount in different cells.

On Broad Top.—I.

WHERE is Broad Top? What is it like; and what do you do there? For many years, as the time approached for our autumnal trip to this out-of-the-way part of Pennsylvania, we have been asked these questions and have found no trouble in answering the first, but the last two are more difficult to explain, for the place is so unlike all conventional mountain resorts. It is not, indeed, a resort in any sense, but a mountain wilderness, happy in having few special features, no points of interest, and little of what the reporters call "fine scenery."

Charles Dudley Warner somewhere speaks of tourists who search for "scenery that ranges from the two-dollar to the five-dollar a day kind," and this is not the place for them, nor can they understand the beauty of these shaded moss-grown roads on the abandoned farms (see illustration, page 571); of the woods and sunny meadows; above all, of the sense of remoteness which forms much of the indefinable charm of the place. It has had devotees in our family for years, since two belated hunters found refuge overnight in the little log-house that not only shelters us when we come to the mountain, but is still the home of the same family who lived in it then. That family, and others scattered at intervals over the mountains, are the remnants of a life that is passing away, a primitive Pennsylvania that will soon vanish as the spirit of "Progress" spreads over these wilds, and railroads, mines and hideous coke ovens invade the "hollows," and the "runs," that have heretofore been so beautiful.

The Broad Top country is a mountainous region with an average altitude of 1,800 feet, lying in Bedford, Huntingdon and Fulton counties, and is the eastern limit of the bituminous coal measures. It is reached on its northern and western borders by the East Broad Top and Huntingdon Railroads, the former connecting with the Pennsylvania Railroad at Mt. Union, the latter with the same road at Huntingdon, and between these two places are some of the boldest and most beautiful mountains to be found along the Juniata.

The southern and eastern borders of the country can only be reached by mail-wagon or private conveyance, as Fulton County does not possess a mile of railroad, though the South Pennsylvania road, if ever built, will cross it and open up to the world its beautiful valleys and mountains. Although the general outlines of the mountains follow the parallel system so noticeable in Pennsylvania, here in the coal country they are picturesquely broken, the valleys in many instances are really deep ravines, taking their names from the streams that run their short but active life through them. These streams were once the haunt of the trout, and their banks the home of the *Rhododendron*, but some of the most wild and beautiful ones are now blackened in their lower reaches by the wash from mines and dumps, and the ravines are made hideous by squalid villages.

The mountains are tremendously steep, but there are few rocky precipices, as in most instances the outcropping rock has been so shattered by the action of frost and time that landslides have been formed, smaller, but like those so noticeable along the Narrows of the Juniata. The mountains have been, and still are in many places, magnificently wooded, and the forest-growth is most varied and interesting; many of the White Oaks are superb, but with the increase of building one fears their days are numbered. The work of the saw-mills is, of course, a necessity, but the waste is so terrible that we carefully avoid seeing one in operation a second time, for it is painful to note the great branches left in the woods and the slabs that are run directly from the saw into the fire. The waste of a saw-mill, however, is a trifle compared with the destruction of the bark-peelers, who, after gathering their harvest, leave the spectral bodies of what were once trees to a slow decay, unbeautiful by the kindly moss which almost at once begins to cover the fallen timber not denuded of its bark.

On the map at the junction of the three counties above mentioned is an irregular expanse marked "Broad Top Mountain," between eight and ten miles long, and varying from two to four miles in width. The greatest altitude, about 1,800 feet, is at the southern extremity. From this head, which is a wilderness miles in extent, enormous arms and "saw-teeth" project boldly into, and separate, the valleys below. The township roads crossing the lower end of the mountain are built along and down these arms, and, except for occasional reaches of Oak-barrens on the higher levels, one may drive for miles in any direction through almost continuous shade. The roads are of two kinds—those that are "wagoned a heap" and those that "hain't wagoned so much"—and we find the pleasantest drives are those where the wagon goes ahead and we follow on foot. The mountain is literally a broad, though by no means a flat, top, and has a little system of its own of inner ridges, plateaus and an upland valley formed by Trough Creek, which rises near its head, and almost equally dividing this inner table-land, flows north until, after a long and devious journey, it empties into the Juniata.

The country was settled about the beginning of the Revolutionary War by English and Scotch-Irish emigrants from Maryland, who took out warrants for land that, in most instances, was held for several generations by descendants of the original settlers until the absorption of the small holdings by the large coal and iron companies.

A good spring was the first requisite for a site, and that once found, land was cleared, log-houses built, orchards planted, until, in a few years, farms, some of them quite extensive, were scattered over the mountains, though at a safe distance from their nearest neighbors, as game was a necessity. About the beginning of this century coal was discovered, and, with the advent of the railroads, that Golden Age, when "a man could open his door at sun-up and shoot a deer in his garden," when turkeys and pheasants ruined the buckwheat-crop, and when no man was considered fit to hold a rifle who shot game anywhere save through the head, disappeared forever.

About 1855 there was a mining and railroad boom. Most of the land passed into the possession of corporations, and the movement has continued until now a few large companies control the country. On Broad Top Mountain, with the exception of a few farms on the northern border, held on leases from the companies owning them, all the farms were, of course, abandoned.

The men who sold them felt themselves the possessors of immense wealth, and, in many cases, simply departed with their goods and chattels, leaving their houses and barns to the elements. Others removed their logs and timber and built elsewhere, but one and all left behind them what was almost imperishable—the restful beauty of the place. The little mountain farm that we have known so long lies within the encircling rim of the mountain, upon a partially cleared promon-

tory of land, that juts down from the upper plateau, between forests that clothe its sides and lower extremity, and conceal two little tributaries of Trough Creek, which unite near its base. With one single exception, the nearest human habitations are more than a mile distant, out of sight and sound, on the outer side of the western ridge.

Wray's Hill, which forms the eastern ridge, does not show a sign of life, and, except toward the north-west, there is not a house within a radius of five miles, though within that same radius are nine abandoned farms and several small clearings. Some of the farms are included in the leases held by two or three families of still occupied farms, and they keep in repair fences about the old orchards, gather the fruit, pasture cattle in the old meadows, and when mountain fires occur are bound to protect the company's property by "fighting fire," whether upon their own or the abandoned farms.

The middle of September finds us, after a railway journey up the always beautiful Juniata, landed in a most unpromising little station in the heart of the coal country, but even the dust and grime of the place cannot conceal the beauty of the hills and mountains surrounding it. We soon find the old wagon, gun-case and camera are stowed away, and we start off for our two hours' drive, most of it a steady climb.

For three miles up the narrow valley the road has lost its original beauty, as the flood of 1889 changed the course of the stream, and covered the valley with the waste from the dumps. Most of the foliage is still as green as in midsummer, but as our road ascends higher and higher, giving us views, now down a deep ravine, then off to the hills, we recognize the familiar landmarks, and finally, after a mile of road that would have driven Macadam insane, we turn the shoulder of our own mountain, and the panorama of what is always our first and last great view is spread out before us. In the right foreground is Round Knob, showing faint tints of gold and flame along a line of Hickories and Maples at its base, and in the distance rises tier upon tier of the Alleghanies until the remotest line is merged into clouds.

Plunging into the woods we continue our ascent on a fairly good township road until we leave it for the series of boulders and rocks that form the road to our destination, for few of the mountain farms are found near the public road. A short climb and we are out of the woods, on the level, and surrounded by the most brilliant, surprising mass of color. The Thorn Locusts and scrub Oaks, which here form a short stretch of barrens, seem to support beds of color, young Sassafras-trees, which are in coloring the counterpart of Parrot Tulips, and are absolutely blazing in the brilliant sunlight. Then into the woods and down a short distance, and as we emerge into the sunlight the little farm is spread before us; the orchard with old cider-press in its corner, Wray's Hill opposite us, the little log-house just as it looked last year, the same Dahlias apparently by the gate. The wagon stops, the same voices rise to greet us, we step down and realize that we are once more on Old Broad Top.

Harrisburg, Pa.

Mira Lloyd Dock.

Late Autumn in The Pines.

I HAVE just returned from a ramble in the Pines, and, notwithstanding the excessive drought during late summer and autumn, I found a greater number of plants in flower than usual at this time of year. The Soapwort Gentian was never more beautiful than now, and good specimens of Gentiana angustifolia were also in the damp barrens, and little *Bartonia tenella* was still in bloom. Some belated flowers of the Meadow Beauty (*Rhexia Virginica*) were looking as if they had forgotten that it was late in November. *Rudbeckia laciniata* was here with long, drooping yellow rays, which looked charming with the blue Gentians. Blue and white Asters were not rare. *A. nemoralis* was particularly good. Two or three species of Golden-rod were also seen in damp places vieing with the Asters in perfection of leaf and flower. The most handsome of these late-flowering Golden-rods are *Solidago sempervirens* and *S. elliptica*; both have smooth shining foliage as beautiful as the flowers.

Along the margin of a pond I found *Coreopsis rosea* still in bloom, and Ladies' Tresses (*Spiranthes cernua*) were hidden among the grasses, bright and sweet as they were a month before. The Bur-Marigold (*Bidens chrysanthemoides*) was abundant in wet places, and it is one of our handsomest late flowers. It has broad deep yellow rays, an inch or more in length, which, together with its connate leaves and long-continued bloom, make it a very desirable plant. The Mist flower (*Conoclinium coelestinum*) was also here with pretty clusters of blue flowers. Coils of matted flowers of the Dodder were still blooming, looking almost like ropes twisted close and

tight around the plants, sapping and drawing the life from their hosts. In the dry upland Pines I found *Chrysopsis Mariana* in bloom, and the pretty blue flowers of *Diplopappus linariifolius* were also here, and looked charming with the yellow *Chrysopsis*.

It is quite remarkable how well the foliage appears on most all of the low-growing plants. Even in the dry barrens, where the white sand looks as if there was no moisture in it, plants seem as fresh and bright as if there had been copious rains. The root-leaves of the Rattlesnake-weed (*Hieracium venosum*) were vigorous, lying in flat rosettes on the ground, each leaf handsomely marked with purple and lighter shades, and making them very ornamental. One of the most interesting plants in the dry sand was little *Lechea minor*; it had grown in many forms, but had mostly assumed the shape of miniature trees, none over a foot in height, yet perfect mimics of their large neighbors, under whose shelter they grew. Some had round dense heads on slender stems; others were forked and branched to simulate the varied forms of forest-trees. And the coloring of the tiny leaves was beautiful, too. Some of the plants were still a vivid green, while others had taken on the bronze and purple of autumn. The grayish looking *Hudsonia tomentosa* was a near neighbor of *Lechea* and was fresh and thrifty; but we know the secret of the good looks of these plants, for their roots reach down deep to the level of constant moisture.

Another interesting plant not at all affected by the long drought is *Chimaphila maculata*. I found thick masses here and there, covering two or three square yards with bright variegated foliage, fresh and shining, and dry seed-pods held above the leaves on erect stems to remind us how charming they were in midsummer when covered with fragrant blossoms. This charming plant, if given the right conditions, can be grown on the home-grounds quite easily. It loves the shade, and if one has not the time or inclination to prepare a place for it, a few plants set beneath the dense shade of a low-growing evergreen will flourish and give great pleasure. Two of my near neighbors have both species of *Chimaphila* growing and flowering in perfection under evergreens where they never set the plants. In all probability they were in the ground when the trees were set, some twenty-eight or thirty years ago, when the place was fresh from the forest. At all events, here they are, with no care, as fine plants as I ever saw. But they are entirely hidden from view, and we can only see them when we part the thick branches of the trees. I am sure a mass of these plants can be grown where they can be seen, and I am preparing a place in an angle of the house where the sun cannot reach them, and they are to be planted in the same leaf-mold where they naturally grow.

The grass-like leaves of *Xerophyllum* do not seem to be at all affected by the drought, and the Pitcher-plants look as fresh as usual even in quite dry places. But the trailing *Arbutus* has suffered considerably, and the leaves of many plants are dry and brown, with long stems entirely dead. *Pyxidantha* is also shriveled and dead in many places.

The foliage is still clinging to many of the deciduous shrubs as well as to some of the trees. The *Vacciniums* are gorgeous in color, and so is *Leucothoë racemosa* and *Andromeda ligustrina*. This brilliant color, mingled with the deep green, shining foliage of the Laurel and Holly, makes lovely and effective passages in the Pines. The large leaves of *Magnolia glauca* are still green, and so are the leaves of the Alder (*Alnus serrulata*). The young Pines (*Pinus rigida*) are looking better than they have for several years past. Something has happened to their insect enemies, so that the trees that were not killed have made a rapid growth the past season.

The little bushy scrub Oaks (*Quercus prinoides*) are holding their foliage, while the acorns have mostly fallen. These acorns are small and round, all nearly of the same size, and when strung on stout linen-thread can be woven in many fanciful designs. At the base of the acorn-cup I often find clusters of little abortive acorns, which I have never seen in any other species.

The fruit of many plants is now at its best, and very handsome. *Baccharis* is one mass of plummy white pappus, and its leaves are still green. The Hollies suffered less than usual from the ravages of the rose-bug this season. The marauders left some of the flowers, too, so that we find berries here and there on the trees. The bright red berries of the Black Alder (*Ilex verticillata*) are abundant, and the grayish fruits of the Bayberry are clustered thickly along the stems among the shining and fragrant leaves. The Bitter-sweet (*Celastrus scandens*) has opened its orange-colored pods, displaying its pretty scarlet seeds. Several species of *Smilax* are full of clustered fruit that will remain all winter long, and the Poison Sumach

has hung out its whitish drooping fruit in tempting array, but, handsome as it is, it cannot be allowed admittance to our collection.

Vineland, N. J.

Mary Treat.

Gardening in the Confederacy.

IN the twist which war times gave to southern life no interest or vocation entirely escaped. Domestic economy was revolutionized. The blockade having cut off the supply of northern and foreign goods, a home-made substitute had to be contrived for every article of clothing, for articles for household and for farm use, and for every article of food except the plainest and coarsest. Wood took the place of sole-leather in shoes, and coarse homespun the place of daintier fabrics. Corn-meal supplanted wheat-flour, and sorghum-syrup became the national sweetening, finding its way into most of the products of the Confederate kitchen, from counterfeit coffee to pound-cake and ice-cream.

Gardening, of course, underwent a change along with other things. Northern-grown seed, which had now come into almost universal use, being no longer obtainable, every housewife was driven back upon the old-fashioned method of saving her own seed. There was a touch of irony in the fact that the few seeds brought in through the blockade were flower-seeds. The demands of the new household economy worked considerable change in the product of the garden. Okra then first came into general use, but I never knew a pod of it to be eaten until after the war, though some families doubtless used it much earlier. We grew it as a substitute for coffee. The dry seeds were collected, parched, ground and infused after the manner of the true Arabian berry. At first okra-coffee had numberless rivals—parched meal, dried sweet potatoes, wheat, rye, and even cotton-seed, persimmon-seed and dandelion-seed—but it finally, I believe, supplanted them all except rye, with which it maintained a strong and lasting rivalry. Not infrequently heated disputes would occur between advocates of these rival substitutes. In fact, some hard-time connoisseurs became so wedded to okra-coffee, sweetened with sorghum, that they were loud in resolves to drink no other even though returning peace should bring back the genuine coffee. And when I add that some of these resolves outlived the war a twelvemonth, it will be seen that there must have been a great deal of earnestness and sincerity in them.

The garden assumed in those scant times a tenfold importance, and great efforts were made to have good ones. The need was urgent that every possible source of food should be turned to account. The tithes and donations to the Confederate Government made deep inroads into all staple products of the farm. Besides the heavy Confederate and state taxes, a tenth of all non-perishable articles of food for man and beast was taken for the armies. What was left, beyond barely enough to feed the denizens of the farm, was liable to seizure on emergency by Government officers. The capacity of the farm was also seriously curtailed by the impressment of work-animals for the cavalry and artillery service and of the negroes as laborers on the forts and fortifications, and, to complete the disaster, the trained and trusted servants were generally the first to fly to the Federal lines. As a consequence, materfamilias had to conduct gardening operations under great disadvantages—sometimes with unskilled hands from the "quarter," oftener still with pickaninnies, scarcely more amenable to discipline than so many wild creatures from the woods.

The energy of the southern women triumphed here as it did over so many other obstacles. Vegetables enough were raised not only for home use, but to give to the numerous families of refugees, which every neighborhood was sure to contain.

Medicine was the scarcest of all scarce things, and, many of the country physicians being absent as field and hospital surgeons, recourse was had largely to such medicinal herbs as the garden could afford, and thyme, sage, horehound and other garden-grown herbs were largely depended upon in sickness. The general health of the people was never better than during these times of scarcity, and this happy result was doubtless largely due to the more general use of simple garden products for food, and the disuse of drugs.

Kittrell, N. C.

O. W. Blacknall.

If the fine art of landscape-gardening is to obtain its most certain and striking effects, it must devote itself to emphasizing natural characteristics. A true park is a place where art has enhanced natural effects, and it can be nothing else. Whatever contributes to better determine or to emphasize natural character is a resource of the art of landscape; whatever destroys, enfeebles or confuses that character the art forbids.—*Hirschfeld's Theorie der Gartenkunst, 1777.*

Plant Notes.

Celastrus scandens.

THIS plant, which is figured in our illustration on page 569, is one of those inhabitants of the forests of eastern North America which, for certain decorative purposes, can hardly be praised too highly, although American gardeners neglect it as they neglect many other beautiful native plants, because it does not come to us from European nurseries, and is not, therefore, expensive and fashionable. The climbing Bitter Sweet, or Roxbury Wax Work, as *Celastrus scandens* is usually called, is a plant that everybody can have, and so it is rarely seen in gardens, although there is no vine hardy in our climate which produces such beautiful and showy fruit or grows more rapidly and with less care.

In its native wilds *Celastrus scandens* climbs over rocks, bushes and trees, delighting in moist shady situations, and often sends its slender twining stems fifteen or twenty feet from the roots. The leaves are abundant, of good size, and of a lively green; the flowers are small, greenish yellow, partly perfect and partly unisexual on the same individual, so that every plant produces fruit. They are arranged in racemose clusters, which appear at the end of the young branches. In this arrangement of the flowers lies the chief advantage as an ornamental plant of the American over the Japanese species, which was figured some time ago in these columns (vol. iii., p. 550). In that species the flowers are arranged in sessile axillary umbels, and the fruit is completely hidden by the leaves until they fall, leaving the branches covered with the open capsules, which are smaller than those of *Celastrus scandens*. But in the case of the American plant, the inflorescence being racemose and terminal, the fruit-clusters, which are often from four to six inches long, stand up well over the leaves and make a great show for several weeks before and after the capsules open. In the late autumn the leaves turn clear bright yellow; and it is at this time that the climbing Bitter Sweet is more beautiful than in any other part of the year, as then the fruit displays its brightest colors and delights the eyes of every lover of nature by the brilliancy and harmony of its contrasting colors.

Celastrus scandens is an excellent plant for covering trellises, to ramble among strong-growing shrubs, or to drape walls and other unsightly objects. It is free-growing without being too rampant, and it is not at all particular about the character of the soil in which it is planted or about the exposure which is given to it. Seedlings are easy to raise, and it may be readily and quickly multiplied by layers.

Foreign Correspondence.

The London Chrysanthemum Exhibition.

ONE week of rain and another of yellow fog have been the unfavorable heralds and accompaniment of our great annual exhibition of Chrysanthemums. Still, bad though the weather has been and is, the flowers are, as a rule, first-rate, and the plants are equal to the best of previous years. Chrysanthemums are, after all, of the very best-tempered garden-flowers, and the conditions must be very bad indeed to cause them to fail. Exhibitions are now being held everywhere, even our smallest towns, and not a few villages, boasting an annual show of Chrysanthemums. The horticultural journals are consequently almost wholly given up to reports of them, and will continue to be so during nearly the whole of November.

Of course, the greatest of all these shows is that arranged by the National Chrysanthemum Society to take place at the Royal Aquarium, Westminster, in November. Here the prizes are valuable, and, as a consequence, the exhibits are from all parts of the country and of the best quality.

The cut flowers are this year, as before, the most sensational objects at this Chrysanthemum show, and, notwithstanding various efforts to break away from the practice,

the still generally adopted arrangement is on flat boards with holes in them for little flasks of water, each flower resting on its shoulders on the board. As a rule, the flowers, especially of the Japanese varieties, crowd each other. Bunches of flowers have been tried, but they do not please. It must be admitted that the Chrysanthemum as generally

the Japanese section, as shown in the various classes, I give their names: Aida, Avalanche, Baronne de Prailly, Boule d'Or, Carew Underwood, Coronet, Colonel W. B. Smith, Edwin Molyneux, Etoile de Lyon, Ethel Paule, Eynsford White, Florence Davis, Gloire de Rocher, Gloriosum, Hamlet, H. B. Ironside, Japonaise, Lord Brooke, L. B.

Fig. 97.—*Celastrus scandens*.—See page 568.

represented on the exhibition-stand is as wonderful as it is unnatural.

The most praiseworthy exhibit of flowers at the Aquarium was the first-prize collection of forty-eight large Japanese varieties, shown by Mr. W. H. Fowler, of Claremont. They were a grand lot, the size, form and finish of almost every flower being exceptional. As they represent the cream of

Bird, L. Boehmer, Madame Baco, Madame J. Laing, Mademoiselle M. Hoste, Miss A. Hartshorn, Monsieur Bernard, Monsieur Freeman, Mrs. A. Hardy, Mrs. E. A. Adams, Mrs. F. Jamieson, Mrs. J. S. Fogg, Mrs. A. H. Neve, Mr. D. B. Crane, Mr. E. Beckett, Mr. Williams, Puritan, Ralph Brocklebank, Ruth Cleveland, Stanstead White, Sunflower, Vivian Morel, W. W. Coles, W. Tricker, W. H. Lincoln

and three others of doubtful names. Other Japanese varieties besides the above, which figured in first-prize collections, were Belle Paule, Bertha Flight, Comm. Mraignon, Excelsior, Fair Maid of Guernsey, Madame C. Audiguier, Monsieur Astorg, Sarah Owen, Umpire and Val d'Andorre.

The first prize for six white flowers of a Japanese variety was awarded to a magnificent tray of Stanstead White, Avalanche being second and third. Six flowers of Vivian Morel won the first prize for a colored Japanese variety, the same variety being second, while Sunflower was third. Certificates were awarded to the following new Japanese varieties: Thrumpton (Tenard), a large dark bronzy red flower of good promise; Beauty of Exmouth (Godfrey), a glorified Florence Percy, which has already been awarded four first-class certificates. The flowers were fully six inches across, and pure white, the florets curiously curled as in the favorite F. Percy, which is one of the very best of the white-flowered kinds.

The incurved section was quite as well represented as the Japanese. The following kinds occurred in three or more first-prize collections: Empress of India, Golden Empress, Jeanne d'Arc, J. Lambert, Lord Alcester, Lord Wolseley, Miss M. A. Haggas, Miss V. Tomlin, Mrs. Heale, Mrs. S. Coleman, Princess of Teck, Princess of Wales, Queen of England. Three varieties, Miss V. Tomlin, Golden Empress of India and Mrs. S. Coleman, were included in no less than six first-prize collections. For six flowers of a white incurved variety Empress of India was a long way first, Princess of Wales being second. A new incurved called Robert Petfield (Owen) was awarded a first-class certificate, as well as the first prize for three flowers of one kind. It is not unlike Lord Wolseley in form and color, but paler. The large-flowered reflexed section was represented by Cullingfordi, Dr. Sharp, Chevalier Damage, Cloth of Gold, King of Crimson, Pink Christine, Golden Christine and Peach Christine. These occurred in several first-prize collections.

The large Anemone-flowered division was abundantly represented, the best of them being Gladys Spaulding, Lady Margaret, Thorpe Junior, Cincinnati, Nouvelle Alviolle and Fleur de Marie. The Anemone Pompons were shown in bunches, three sprays of each kind, not disbudded. The best of these did not seem to be first-rate, although the light in the building was so bad by the time I got to them that it is scarcely fair to express an opinion upon them.

The aquarium is roofed with "Duroline," a patent substitute for glass, and which is made of finely woven brass wire, thickly coated with a yellowish semi-transparent substance not unlike a thin layer of gutta-percha. It is durable, and allows a certain portion of light to pass through it, but the color of the flowers is affected by its yellow tint. This was most noticeable on Mr. Cannell's magnificent collection of flowers of Zonal Pelargoniums, which were of the most extraordinary colors as seen in the Aquarium, except when the gas was lighted. Duroline is a most useful invention, and I shall not be surprised to see it become of considerable service in horticulture, but as a roofing for buildings, in which flowers are grown or exhibited, it is not suitable.

Mr. Cannell's Pelargoniums were even better than any I have ever before seen from him. Immense trusses of large flowers, the petals thick and velvety, and the colors rich, as though they had been developed in July instead of under the influence of November fogs and bad light. I noted some of the best of them, and if any one wishes to have in November a rich harvest of most useful flowers I would recommend him to get a collection of these Pelargoniums, and, if possible, learn from Mr. Cannell or some other expert grower how they should be treated. The kinds I noted were Birthday, white, pale pink eye; Ethel Lewis, Beauty of Kent and Amphion, three beautiful soft pinks; Madame de Bourdeville, white, shaded and lined with salmon; Rev. E. Harries, large, vivid scarlet; Lady Brook, white, with a large eye and radiating lines of pink; White Lady, pure white; Stella Massey, flesh-pink; Mascagni,

flesh-colored, with a salmon eye; Sunbeam, deep salmon-red; Swanley Gem, scarlet, with white eye. Mr. Cannell showed about a hundred bunches, each as large as a man's head, and they were tastefully arranged upon an irregular bed of wood moss, the dark green of which had considerable effect in heightening the colors of the flowers.

Fruit, vegetables, cut flowers and table-plants were all represented by very fine collections. Messrs. Suttons' prize competition for vegetables raised from seeds supplied by them produced a great display of gigantic well-grown carrots, cauliflowers, leeks, potatoes and everything else good and seasonable in the vegetable line. Such exhibitions serve the purpose of a grand advertisement and at the same time give the general public some idea of the perfection to which vegetables may be grown. Of course, we must always bear in mind that a good show-vegetable is not necessarily a first-rate one for the table.

In conclusion, I may say that the best of the new Chrysanthemums at the exhibition was, in my opinion, Beauty of Exmouth, and the most striking in the whole of the collections were E. Molyneux, Vivian Morel, the greenish Florence Davis, and Sunflower. Of course, all the Queen family of the incurved kinds were supreme as ever. Messrs. Pitcher & Manda's prize of £20 for the best seedling raised from the exhibitor's own seed was awarded to Mr. W. Gilbert for a Japanese seedling unnamed. Other certificated new kinds besides those already mentioned were Dorothy Shea (Shea), a cross between E. Molyneux and Sunset; Mr. C. Shrimpton (Shrimpton), a chestnut-red Japanese variety; Charles Blick (Blick), rich yellow, with broad petals; Rosy Morn (Carter & Co.), a Japanese rosy purple, large-flowered variety; Ed. Lonsdale (Pearson), crimson Japanese; Brookleigh Gem (Caute), a purplish sport from Jeanne d'Arc; La Deuil (Jukes), a Japanese Anemone, flowered variety, large, full, crimson-purple.

Propagating New Strawberries.

OF all the occupations or pastimes of the horticulturist the originating of new varieties of Strawberries is one of the most fascinating. The method is so simple, and the result so speedy and apparent, that it never loses its charm. Besides, there is always a chance that something of real value will be produced.

With scarcely an exception all the kinds of any value now in use originated in the judicious crossing of different varieties, so as to unite as many good qualities and as few poor ones as possible in the same plant. Many had their origin at haphazard from the chance crossing of nature, but few have stood the test of time. The Hoffman was found growing in a hedge near Charleston, South Carolina, and it was a find of unusual value. While not perfection in itself, it may prove the variety from which the ideal berry of the future will be derived. It has size, color, firmness, and adaptiveness to different soils and climates in a marked degree; its extreme earliness is another valuable quality, and it needs only greater productiveness.

Varieties selected for crossing should have diverse merits, so that, if these merits are combined in a single seedling, this would have the greatest possible number of good qualities. This ideal berry will possess, in eminent degree, size, earliness, productiveness, flavor, attractiveness and firmness. The market gardener, as a rule, requires size, earliness, productiveness and attractiveness, and if he lives remote from market, also firmness, so that his berries will carry well. The amateur gardener above all desires flavor, with productiveness and size as close seconds, and with earliness and beauty not far behind. The Hoffman has good size and is early. In the Bubach, Sharpless and in other varieties flavor, or at least palatableness, as well as largeness and productiveness, are to be had. Possibly the long-sought berry may be an offspring of the Hoffman and Bubach, which possess, together, about every desirable quality.

To achieve this result my plan is to set a sufficient number of the pistillate Bubach plants in a Hoffman field where their blooms will be thoroughly impregnated by the pollen from

that staminate variety. If these operations are bounded by the limits of a garden, extreme care must be used to prevent the intrusion of undesirable pollen from other near-growing varieties. Nothing in nature is more subtle and penetrating than this impalpable dust. If other varieties than the two to be crossed stand within one hundred yards a sash should be used as a protection. This may be placed just before blooming-time over half a dozen plants each of the chosen kind set the autumn before. A camel's-hair brush is used by some

fourth of an inch deep. In watering, a sprinkler with a fine rose will prevent the washing up of the seed. Germination should begin in two or three weeks. When large enough to bear it, they should be transplanted, in wet weather, to good soil. With good soil and attention these plants will probably bear some berries the following spring, but nothing decisive should be expected until the second bearing season. Meanwhile, all runners should be clipped as fast as they appear.

The result of an experiment of this kind will be curious and interesting if it has no other value. While the berries of every plant will in some degree resemble one or both of the parents, no two will inherit exactly the same qualities or be precisely alike, and each will have its own distinctive qualities.

The desirable plants should be marked, or the undesirable ones may be destroyed. Those retained can now be allowed to produce runners at will, care being taken to prevent those from any two plants mingling, so that they cannot be distinguished. The runners from each separate original plant will bear the same kind of berries and constitute a new variety.

Kittrell, N. C.

O. W. Blacknall.

Fig. 98.—Road through a Chestnut Wood on Broad Top.—See page 566.

propagators to convey the pollen from the staminate to the pistillate blossom, the plants being kept in pots.

The berries once well "set," all danger of further intermixing is past, and, of course, no other preventive measures need be taken to keep out other pollen. From thoroughly ripe berries borne by these plants the earliest and largest should be selected. After the pulp is expressed the seed should be sown in rich, well-prepared soil, and covered with fine earth about one-

A few Notable Shrubs in late November.

THE Thursday of the last week of November is now generally looked upon as the Thanksgiving Day of the American people. In the south the frosts generally have not then caused any very great destruction of vegetation, and late autumn flowers may linger until Christmas. But in northern gardens, November frosts are usually frequent, and often very severe, and Thanksgiving Day brings with it few fresh flowers to be found in the open air. The Fall Dandelion (*Leontodon autumnale*), so common in our fields, is one of the most persistent plants in continuing to produce flowers in spite of frost, while Tansy and some others of the Composite family are more likely to maintain their freshness than any other class. Precocious flowers, not due until the following spring, are not very rare, and we sometimes find Dandelions in cultivated ground, Daphnes in our gardens, and, perhaps, *Epigæa* in our woods bearing a few stray flowers.

But it is the fruitage of certain shrubs which will attract most attention as autumn passes into winter, and probably the number of species available which possess this quality is not generally appreciated. Every one having any sense of color admires the abundant fruit of the common Barberry, which now grows so commonly along many waysides. But there are other species of Barberry, as yet unknown to the majority of gardens, which surpass our common kinds in the lasting beauty of their fruit. By far the best of these is the Asiatic *Berberis Thunbergii*, the bright red berries of which, being comparatively dry and juiceless, remain in perfect condition all winter, while the juicy fruit of the common Barberry becomes shriveled by frequent freezings and soon loses color and lustre.

For brilliant red color we have our native deciduous Hollies, or Black Alders, or Winterberries as they are also called. These thrive as well under cultivation as the Barberries, and may be taken directly from their native haunts and planted in the shrubbery if necessary. As they are diœcious—the male and female flowers being produced on separate plants—it is necessary that care should be taken to select fruiting plants in order to secure a crop of the showy berries. There does

not appear to be any great difference in the size and ornamental quality of the fruit of the common Winterberry (*Ilex verticillata*) and the smooth one, *Ilex lævigata*, but the berries of the former are usually more abundant, they ripen later, and they persist longer in a bright and showy condition. These and the Barberries might furnish enough of the bright reds in any group, but they may be augmented by still others of similar colors. Besides one or two more southern species with red or scarlet fruit which prove hardy in our northern gardens, there has been introduced to the Arnold Arboretum a Japanese species which is quite ornamental after the leaves have fallen, which they do early. This was received without a name some years ago from the Flushing nurseries of Messrs. Parsons, and from descriptions it appears to be the *Ilex Sieboldii* of Miguel. The fruit is much smaller than that of our native species, but is produced in abundance on slender branches and twigs. A peculiarity of these fruit-bearing twigs is that two of them are often produced from the axil of a leaf, one being superposed immediately above the other. This gives the shrub a particularly twiggy aspect. In striking contrast to the normal red or scarlet of the fruit of these different Winterberries is a clear, bright yellow-fruited form of *Ilex verticillata*, which was found some years ago near Andover, Massachusetts. It bears fruit in abundance and is singularly showy at this season.

The Burning-bushes, or species of *Evonymus*, are better known than most shrubs which are valuable for late autumn effects in color; but the closely allied Bittersweets or *Celastrus* are not often seen except where they grow wild. The native species, *Celastrus scandens*, with its deep orange pods and scarlet arils, is unlike any other species in cultivation, and in some respects is better than its Japanese congeners. As it is dioecious, care should be taken to procure stock by division from fruiting plants, for if the plant should be a staminate one it might grow rampantly and blossom, but would produce no fruit. The best known of the Japanese species is probably *Celastrus articulata*, which has much smaller berries than *C. scandens*, with yellow instead of orange-colored pods. It makes an excellent covering over rough places and rocks, as it is of rather rank free growth.

Roses of various species sometimes have fruit of quite an ornamental quality at this late season, and the hips of *R. Carolina* may be taken as an example. The Cotoneasters are a group of shrubs almost unknown in American gardens, probably because they are not conspicuous for flowers. The fruit of such species as *C. vulgaris* and *C. acuminata* remains of a rich purplish or reddish color after the leaves have fallen, while *C. Simoni*, still holding some of its foliage, has fruit almost scarlet in color. The purplish red fruit of the Chokeberry (*Pyrus arbutifolia*) is fresh enough to be ornamental; and although the large yellow Japanese Quinces have fallen, they perfume the air on a mild day if they have not already been gathered for making jelly, as they can be converted into a fairly good table dish.

The high-bush Cranberry (*Viburnum opulus*), too, is not to be overlooked, and, besides the brilliancy of its bright red fruit, it may also serve a useful end as a sauce in regions where the true Cranberries will not grow. The Coralberry, or Indian Currant (*Symphoricarpos vulgaris*), which is as common as a weed in some places, is deserving of recognition on account of its slender branches being laden with the small dark red or magenta-colored berries, in striking contrast with the large snow-white fruit of the allied Snowberry (*S. racemosus*), which usually does not keep its fruit so late into the winter. For a shining black fruit the Common Privet is unexcelled; and the large egg-shaped scarlet berries of the so-called Chinese Matrimony Vine (*Lycium Chinense*), hanging thickly on the long string-like stems, are a surprise and delight to every one who sees them for the first time.

Arnold Arboretum.

J. G. Jack.

Orchid Notes.

THE genus *Dendrobium* is so extensive that there are always some of its representatives in flower. *D. chrysanthum*, the golden *Dendrobium*, is just fading, after having been in bloom for the past six weeks. The pseudo-bulbs of this plant are long, pendulous and of medium thickness, and the flowers are produced with the leaves on those of recent formation. These are oblong-lanceolate, from four to five inches long, and of bright green color; and the deep yellow flowers, with dark brownish blotch at the base of the lip, are two inches across, borne on pedicels two or three inches long and in clusters of two or three at the nodes of the pseudo-bulbs. This species has two distinct flowering seasons, autumn and early spring, and it requires a warm-stove temperature. It should have

about three weeks of complete rest after flowering, and then, with heat and moisture, it will start into vigorous growth.

Dendrobium formosum is a remarkably handsome plant, now flowering freely. The stout pseudo-bulbs are well clad with deep green oblong leaves, bearing the large blossoms in dense racemose clusters of three or four at the apex. The flowers are from four to five inches in diameter, pure white, with a large irregular patch of deep orange-yellow on the spreading lip. This plant is, reputedly, difficult to manage, but its conduct here is quite satisfactory. It is rested moderately after flowering—that is, it is placed in a minimum temperature of fifty-five degrees, Fahrenheit, and kept sufficiently moist at the roots to prevent the leaves from shriveling. The plant is fully exposed to light and sunshine, and the surrounding atmosphere is kept as dry as possible. It is turned out of the basket in spring, and replanted with fresh rough peat, charcoal and sphagnum about the roots. Then it is placed close to the glass in a house where the average temperature is seventy degrees and the air is continually laden with moisture. This is maintained, with frequent applications of water, and shading from bright sunshine, until the new growth is completed, when the plant is again subjected to the cooler treatment until the flower-buds are well advanced. It is then given a slightly warmer place for the flowers to develop.

The flowers of *Cœlogyne fimbriata* are pretty, though not very showy. The plant is rare in gardens, but well worth cultivation, as it is ever green and fresh in appearance, and always blooms freely late in autumn. The racemes emerge from the apex of the pseudo-bulbs, and they are slightly shorter than the leaves. The peduncle bears three or four flowers about an inch in diameter, developed in quick succession from the base upward. The sepals are ovate-lanceolate, the petals linear, and both of a yellowish green color. The trilobed labellum is very beautiful. The lateral lobes are erect, the front one spreading and prettily fringed. The ground color is a trifle paler than the other divisions, and there are many prominent lines and patches of rich velvety brown on the upper surface. The blunt, curved column is bright yellow at the tip, thus completing a combination of color that would be called highly pleasing were the picture magnified a few times. The freedom with which the flowers are produced compensates for the deficiency in size. *C. fimbriata* is easy to grow, and thrives luxuriantly in a well-drained pot or pan, with peat-fibre and sphagnum about the roots. The sphagnum should always be kept moist. An intermediate temperature gives the best results.

Cambridge, Mass.

M. Barker.

Basket-plants for Window Culture.

THE cultivation of basket-plants in living-rooms is necessarily somewhat limited, from the fact that many species that show to advantage under this method of culture are not best suited in the dry atmosphere of a dwelling, for the soil in a basket will naturally dry out under such circumstances much more rapidly than pot-grown specimens, and in all cases the plants so grown, if in good health, will be found to require thorough watering frequently, the most satisfactory method being that of dipping the entire basket in a tub of water, and then allowing it to drain off in a sink or other convenient place before returning it to the window garden. There are, however, a number of species that will thrive under all these disadvantages, and prominent among them is *Othonna crassifolia*, a pretty little composite with bright yellow star-like flowers about half an inch in diameter. This is quite a rapid grower when placed in a sunny window, and soon covers a basket with a screen of its slender shoots, which are clothed with bright green leaves of very succulent character. It is readily propagated by cuttings, and it has the good quality of not being easily discouraged by slight neglect, and overwatering is more detrimental to it than an undersupply.

The Variegated Ground Ivy (*Nepeta Glechoma variegata*) is also a very useful subject for our purpose, and, though a common plant, it is one of real beauty, its small, kidney-shaped leaves being prettily variegated with white, while its growth is profuse under reasonably good conditions. This, also, is easily increased by cuttings, and, besides, being a good basket-plant, the *Nepeta* can be used to advantage for carpeting the surface of a window-box or for covering the soil around a large pot specimen—for instance, a large Palm or other decorative plant.

Fuchsia procumbens is another pretty little plant for house-culture, and of rather different type from the general idea of *Fuchsias*, being a trailing plant with small roundish leaves and erect tubular flowers, which are rather insignificant in size and yellow and blue in color. The flowers are succeeded by crim-

son berries, which remain on the plant for a considerable time, and add much to its decorative value. *F. procumbens* is a cool-house subject, and can, therefore, be grown in some windows in which more tender plants would suffer from the low temperature.

The Ivy-leaved Pelargoniums are also admirable plants for window-decoration, combining beauty of leaf and flower. Marked improvement has been made in the later introductions among this charming group. Among the older varieties *L'Elegante* still holds its own as a handsome variegated-leaved sort; in fact, it is doubtful if there is a finer-foliaged variety in cultivation, its combinations of white and pink found in the variety being most attractive. The chief improvement aimed at in the newer varieties has been in the flower, and much has been attained, both in single and double flowers, the foliage in most cases being bright green, and more or less marked with a bronzy zone.

It is scarcely necessary to note the value of German Ivy (*Senecio mikanioides*), the *Tradescantias* and *Saxifraga sarmientosa* for the purpose in view, their merits being already so well recognized for basket-plants, while their propagation is also well understood by all plant-lovers. Some Ferns can also be grown in window-baskets with success, two of the best for the purpose being *Nephrolepis exaltata* and *N. davallioides furcans*. Both are strong growers and withstand the dry atmosphere of a dwelling quite well, providing their roots are not allowed to get dry. They belong to the Sword Ferns, and have long, graceful pinnate leaves, often four feet long in large specimens, and as these plants send out stolons or runners, somewhat like a Strawberry, it is not difficult to increase them.

Chrysanthemums Naturally Grown.

NOW that severe weather has blighted the last of the flowers in the border it may be well to say something about the Chrysanthemum in the garden. The seasonable notes in the horticultural press mostly give only one phase of Chrysanthemum culture, that under glass, and generally the cultural directions are only meant to aid in the production of the largest possible flowers. From one point of view this is entirely satisfactory, but the owners of spare glass are few, and there are those to whom mammoth flowers are not all-satisfying. With the keenest appreciation of the best efforts of the cup-hunter, one feels, after visiting the various growers, that the matter becomes somewhat tiresome. Every one grows them on the same plan with not largely differing results, and to see one lot is to see them all. With all the variety in the houses of the grower of large flowers one could never gain an idea as to the abounding wealth of form and variety to be found in the family.

To one who loves a garden with all the flowers of the various seasons, the Chrysanthemums are indispensable for the ending of the floral year. There are no plants which, for the same care and attention, will give a more satisfactory and abundant harvest. They may be flowered in the garden in this latitude with temporary shelter, which may be arranged at slight expense, a necessity which they well repay. For some years I have so grown them, protecting them sometimes under sash, and sometimes under a tent. Hot-bed sash on a temporary frame are the most satisfactory, as a tent is a difficult subject to anchor and cools off too rapidly under a high wind. It is scarcely possible to secure exhibition flowers under such conditions, but one can easily obtain really fine blooms, and quite as large ones as are useful. Flowers so grown are mostly lacking in depth, which is only obtainable by culture where all the conditions can be controlled, with manuring, watering and like processes carried on without regard to conditions of outside temperature. Where they are partially exposed, there will, of course, be days when these attentions could not be given safely, and the plants have to be kept generally on the side of dryness after the middle of October. Flowers grown under these conditions, freely exposed to the air when the temperature is above the freezing point, though protected at all times from high winds, are to me the most satisfactory and enjoyable, as they seem entirely in character. After roughing it for about a decade with Chrysanthemums in the garden, those under glass seem to me about as tame as a deer in a paddock. There are many flowers which please me as well as the Chrysanthemum, but none which so excite or exhilarate me as these in a bright frosty October day. Under such conditions, with the beautiful forms, the wealth of color and the faint odor, they are fairly intoxicating. This is not an effect singular to myself, as I have noticed after some experience

with visitors. A few years ago, when my collection attracted some local interest, it first amused, and then puzzled, me to see very frequently rather indifferent visitors to the Chrysanthemum shows become enthusiastic over my flowers, which were only mediocre ones in comparison.

The explanation was simply that here they felt and were stirred by the real spirit of the flowers under their natural conditions.

For out-of-door culture the grower will find that some care will be necessary in selecting his varieties, those with not too thick a petal being the most desirable. Varieties with meaty florets are quickly ruined by a light frost, and in many of the modern varieties, favorites with the growers of lasting blooms are of this character. Otherwise one can scarcely go amiss in selecting according to favorite colors or types.

Elizabeth, N. J.

J. N. Gerard.

Sonerila Hendersoni.—The dwarf, compact habit and pretty foliage of this plant renders it very useful and telling in the outer line of a group of larger plants or along the margins of our stove stages. It first came into notice early in the seventies, and was at once stamped a popular favorite. In habit it is branching to an extreme degree, and the height seldom exceeds six inches, being often less than that. The ovate, opposite leaves, with short petiole, are from three to four inches in length, and closely arranged on reddish stems. The underside is light green, freely-marbled with reddish purple, and the upper surface rich dark green, suffused and dotted with silvery white, the spots being more distinct in the older leaves. The plant has an additional charm in the beautiful flowers, which are produced in large numbers during the autumn months. They are borne in three or four-flowered umbels at the extremity of the stems, thus having a most effective setting in the pleasing foliage. The peduncles are from one to two inches and the pedicels one-fourth of an inch in length, and the three-parted corolla, with oblong divisions, is of a deep pink color, and an inch and a half wide, the showy yellow stamens being arranged in a cluster in the centre.

Sonerila Hendersoni is extremely easy to cultivate. It is most ornamental and serviceable when grown in pans three inches deep and six inches across at the top. These should be well drained, and filled to within half an inch of the rim with a mixture of loam, peat, leaf-mold and sand, in equal parts. The soil should be pressed down firmly and covered with a light coat of sharp sand. In this cuttings should be inserted early in spring, placing them about two inches apart. The pans may then be stood in a close propagating-frame, where the cuttings will strike root in a short time. When the plants have fairly started into growth, they may be at once removed to the stove-stages. An average temperature of sixty degrees insures healthy development, and the plant likes a moist atmosphere and a position near the glass, with shade from brilliant sunshine in summer. The statements regarding the origin of *S. Hendersoni* are contradictory. Some authorities say it is a garden hybrid, while others class it as a variety of *S. margaritacea*, introduced from the East Indies in 1875.

About Irises.

To the Editor of GARDEN AND FOREST:

Sir,—It has seemed to me that the Iris is a flower of such variety and beauty, of such hardiness and ease of cultivation, of such value in a formal garden or in wild plantations, as to rank but little below the Rose in its interest to amateurs, yet, so far as I am aware, there is no good comprehensive treatise on the genus, while Rose-gardeners may select their books of instruction from a long list. I have thought that a comprehensive treatise ought to be prepared for American growers of the Iris, which should give specific information in regard to the treatment of the separate varieties, and should be in such a form as to make a pamphlet or small book when gathered together.

Some days since I was talking to a prominent amateur about the advantages of the Iris, and he said to me, "What a pity that their season is so short." But we can cut the superb blooms of the Mourning Iris in May, and those of the Kämpfers and others until August; there must be a way of so choosing and planting our varieties as to give us flowers for nine or ten weeks. We may not be able to get a continued succession of blooms in the same location, on account of the different treatment demanded by different species, but we

should be able to supply our houses with the exquisite flowers for at least two months. Those who have only seen the Iris in a formal garden, or even in a mixed border, can form no idea of its value and beauty in the wild garden when it thrusts up its bloom on the bank of some quiet pond, to be reflected in the clear water, or mingles its flag-like foliage and exquisite flower-colors with the rank growth of a swampy nook.

All who have grown Irises have felt the want of reliable information. Those who have not should have their attention drawn to a source of horticultural pleasure about which it would be difficult to say too much.

Westbrook, L. I.

C. B. W.

[The desire here expressed for information as to this interesting family of plants is likely to be soon gratified to some extent by the publication of a handbook of the *Irideæ*, by Mr. J. G. Baker, which we believe is now in the press. Such a handbook has long been much wanted. Information as to the Iris has been hitherto found mostly in the form of monographs or notes in the horticultural papers, or in "the proceedings of societies," or, in a scientific way, in the encyclopedias. The letter of our correspondent emphasizes the fact that in gardens usually the only Irises known or grown are the hybrids or so-called German, the Japanese, and possibly sometimes the English and Spanish. This is in spite of the fact that these plants have always been special favorites with the lovers of hardy plants, in whose gardens the Iris occupies the place corresponding to that occupied by the Orchids in collections grown under glass. While the Irises are not exhibition flowers and not adapted to making a stir among those who esteem flowers according to their exhibition value, the possessor of a good collection from the hundreds of species of the genus finds them perennially fascinating, usually a feast to the eyes, often of great interest botanically, and very frequently most difficult subjects to flower successfully. Our readers will recall the fact that we have given much space to these flowers; that we have noted the flowering of numerous varieties; have kept up a current history of the Iris season from February till late summer, after which there is a dearth of bloom outside till Iris *stylosa* puts out its flowers in early winter. Numerous Irises are not hardy here, but in the cool house the season can be continued till frost again slightly loosens its hold. One who is fond of plants or flowers which will ornament his garden in all seasons, and who yet wishes mental recreation in collecting and studying variations of species, will find in the Iris an abundant and interesting occupation which seems practically limitless, as new species are constantly being discovered. The genus, too, offers an almost untrodden field for the hybridizer, as work of this sort has as yet been attempted with very few of the species.—Ed.]

Dolichos Japonicus.

To the Editor of GARDEN AND FOREST:

Sir,—The article in your issue of October 26th on *Aristolochia Siphon* leads me to say that I have found *Dolichos Japonicus* a more satisfactory vine for trellis or wall or brush-heap, since it is a more rapid grower and the leaves have a remarkable beauty in their shades of green. I have had it in different locations during five years past, and the only trouble has been that it has outgrown all accommodations provided for it, running rampant and throwing out in all directions its feelers or tentacles, for it almost seems to have animal intelligence, to embrace and cover everything within its long reach. Three vines now cover the tower of my house, running up over forty-five feet. By fixing a point of departure this vine could be fairly seen to grow, as an hour-hand on a watch can be seen to move by careful watching. Some days showed over thirteen inches of new growth! These vines were on the corner, where they are simply to run around a balcony at the first floor. It is not a good "architectural" vine for fronts of houses, but this year I gave it rope up to the loggia, and it was not satisfied with that, and would, I think, have romped clear over the top of the tower-roof if it could have got a leader up over the eaves. The blossoms of this Bean are purple and lavender, but show only from inside; and, by the way, the inside is, without question, the most desirable place to enjoy the vine,

as the light coming through the leaves brings out the delightful greens of the foliage. A rear piazza, therefore, covered with it would become a well-protected light green bower.

Hartford, Conn.

A. H. Olmsted.

[This plant was one of the introductions of Thomas Hogg, which has been sent out by nurserymen under the name of *Dolichos Japonicus*, a name which was once applied to *Wistaria Chinensis*. The plant is, without doubt, *Pueraria Thunbergiana*, an Asiatic twiner of very rank growth. In New England it rarely flowers, and, unless well protected, the stems die to the ground in winter. In milder regions they would survive, since they are distinctly woody, though soft and pliant. Mr. Thomas Meehan writes that his plants in Germantown formerly died to the ground, but within the last few years some ten or twelve feet of the vine have survived the winter. The plant was at one time called *Pachyrhiza Thunbergiana*, and it has had several other synonyms.—Ed.]

Wood Roads on Cape Cod.

To the Editor of GARDEN AND FOREST:

Sir,—The following words, which occur in Professor Shaler's article called "The Betterment of Our Highways," printed in the October *Atlantic*, are of special interest to us dwellers near Cape Cod. "Many of the worst roads in this country," he says, "are brought into their abject state by an unreasonable interference with natural processes—an interference which arises from an ignorant prepossession that all roads should have the same general aspect. Thus, in sandy regions, such as those in south-eastern Massachusetts, and in many other districts near the southern margin of the area occupied by the ice during the last glacial period, the first wagon-roads belonged to the class which we may call trackways, in which the path was just wide enough for a single vehicle, with occasional turn-outs to permit wagons to pass each other. On these trackways a single pair of parallel ruts were quickly formed, the growth of bushes and low forest-trees pressing so close to the roadway as to form a wall of foliage on either side. In many cases the crease made by the hubs of the wagons could be distinctly traced in the thick-set vegetation. Roads of this description afforded excellent wheeling and were maintained almost without cost. The falling leaves and small branches were swept into the ruts, and there mingled with the sand, forming a compact and elastic foundation for the wheels. The sandy soil permitted the rain-water quickly to drain away, so that no gutters were required. Although an unreasoning desire for improvement has led to the widening of almost all these old-fashioned trackways, we may here and there find bits which have escaped the merciless hand of the uneducated road-master. The present writer is accustomed frequently to pass over a stretch of road which was originally all of this nature; but a part of it has been altered to the regulation width of forty feet, while another portion remains in its primitive state. On the improved road the constantly shifting sands are not readily to be passed over by a pair of swift horses drawing a light wagon at a greater rate than six miles an hour. On the more ancient and natural type of way it is easy to attain twice that speed."

If Professor Shaler will come to the shores of Buzzard's Bay next summer, I shall be delighted to show him miles upon miles of these old-fashioned wood-roads, untouched by improvement, and unprovided even with turning-out places, the rather wide spacing of the trees in most places permitting one's infrequent opponents (I do not know what other word to use) to turn out comfortably enough into the low growth of bushes. I put the matter in this way, as a deserved tribute to the chivalry of the farmers of this region, for I have very rarely found that, when they saw a lady driving toward them, they were willing to lay even half the task of turning-out upon her.

There are, I say, very many miles of these roads in this neighborhood, running in all sorts of criss-cross directions between the greater and the lesser highways. As each stretch usually serves only one or two retired farms, which produce little but poultry, market-produce, hay or firewood, there seems little danger of their immediate "improvement." But some are more important and therefore more in danger, and so I offer my little appeal for them as a postscript to Professor Shaler's more influential one. These roads with their three ruts, one worn by the horse and two by the wheels, often with tall grasses and flowers growing between them, afford far better "wheeling" than most parts of our highways. "The

roads here are so poor that I don't care much about driving," says many a new-comer. "They seem so to you," we old-timers reply, "because you probably keep to the highways." "Of course," is the answer, "the less important roads must be even worse." In a city man this reasoning is natural; but it is greatly mistaken. Many of our woodland roads are quite delightful to drive upon; and taken altogether they are better than are our high-roads as a whole, although here and there, near the towns, we have some good solid bits of highway to show. Only, if Professor Shaler comes to try them, he must be content with my one-horse buggy. He must not bring his own pair of trotters. For—as I think I have already told the readers of GARDEN AND FOREST—our wood-roads have their three ruts very clearly defined by the passage of vehicles, mostly belonging to small farmers. A pair of horses can traverse them without great discomfort; but they are meant for a single steed; and the pair is apt to do much damage to the pretty alternating ribbons of grass, Golden-rod and Aster! And, as Professor Shaler knows, our axles are eight inches wider than the axles of Boston Town; so that, in his own carriage, he could profit by only one of our three comfortable shallow ruts.

Marion, Mass.

M. G. Van Rensselaer.

The Niagara Reservation.

To the Editor of GARDEN AND FOREST:

Sir,—The botanist who visits Niagara Falls is constantly attracted away from the striking features of the river and cataract to admire the remarkable development and variety of the plant-life that is everywhere manifest. Especially is this true on Goat Island, which is now one of the few spots in this vicinity that are covered with primeval growth. It is probable that even here the earlier timber has been removed, for that which remains is not very large, but the absence of stumps shows that no cutting of trees has taken place for a long time. The timber is chiefly of the ordinary hard-wood trees, Beach and Maple predominating, with an occasional Oak, Ash or Tulip-tree, and near the paths many small Cedars, white and red, Hemlock and prostrate Yew-bushes.

The long period of neglect which preceded the erection of the Falls into a state reservation was favorable to wild growth, and it is the avowed plan of the present management not to "improve" the locality more than the necessities of travel require, still there is evidence this year more than ever before that the gardener is at work here and there, and may sometime enter upon a warfare against the wonderful wild growth of Goat Island. It is at the close of a fall like this one that the region is most attractive. Up to the last week in October not a leaf had been touched with frost. Though not so brilliant in hue as autumn leaves become under frost, the yellow hues were everywhere, and in great variety, while the Sumachs, which form a grove on the south-east of the island that is striking at any season, do not wait for frost, and produce reds and yellows that are fairly flaming.

It may be said almost literally that no wild plant known hereabout is lacking to the flora of Goat Island, and especially is this true of plants of the more wayward and vagrant tendencies. In few other places does the Wild Grape climb so high or spread so far or swell itself into such tree-like proportions. Nowhere, especially on the American side and in the vicinity of Luna Island, is the visitor out of sight of these rampant vines. The slope leading down to Luna Island is covered with small trees so overgrown by vines that one wonders how the trees can grow at all, yet they appear to thrive under the load.

If the Grape-vines are without fruit this fall, it is not the case with other wild plants on Goat Island. The Virginia Creeper, Bitter Sweet, Waahoo and Barberry are purple, yellow and scarlet with berries, and grow as though this were their chosen home of all the earth. The Barberry here, especially, illustrates the tendency of certain plants to keep away from cultivation. By far the finest specimen on the island hangs so far below the Luna Island stair-landing that it is unsafe to try to gather the rich clusters of scarlet berries, while a bush on the roadway that has been planted and given some cultivation is far less vigorous and seldom bears more than one or two berries on a single stem. The largest Bitter Sweet clusters hang far over the western bank, growing in very indifferent soil, and the Waahoo is best content where left entirely to itself.

Goat Island contains a deep and mostly rich soil, which most of the other islands do not, and it will always retain its remarkable flora if the state officials will let it alone. Their terracing operations in the vicinity of the cottage near the entrance of the island, and the thinning out of the trees between Luna Island and the Biddle Staircase, look extremely ominous. If they go much farther, it will be time for the lovers of nature

to cry out. Already the erection this year of a monster pile of brick work, the first of many factories that the great tunnel must attract if it succeeds, presages the day when the town, even now rapidly growing under the new inspiration, is to be a manufacturing centre, with Goat Island for its chief breathing-place, so that the town, as well as the world at large, will be greatly the loser if the island is robbed of a single one of its distinctive natural attractions.

Buffalo, N. Y.

John Chamberlin.

Periodical Literature.

In the current quarterly number of the *Journal of American Folk-lore*, Dr. D. G. Brinton gives his recollections of a childhood spent in the southern portion of Chester County, a few miles north of "Mason and Dixon's Line," the time being about forty years ago. It was a region of large farms, cultivated by negroes, many of whom had come from the adjacent slave states, the white population being almost entirely American-born, and the general intelligence being above the average in the state, owing to the interest in popular education taken by the original settlers, who belonged to the Society of Friends. Much of the folk-lore of the region, says Mr. Brinton, could be traced to the negroes, but some of it had other sources. "Thus many of the farmers observed the phases of the moon in the planting and sowing of crops, in felling timber, in cutting weeds, in the renewal of their live stock, in the preparation of the soil, and in the killing and curing of meat for food." There can scarcely be a doubt, he explains, that these superstitions "descend directly from that remote period when the moon was the goddess of moisture, the field, the growing crops and reproduction in general. Just such superstitions prevail in France, and the eminent Arago thought it worth while to direct a treatise against them. Many of the superstitions which Grimm narrates as occurring among the Scotch and north Germans, were familiar beliefs. . . . If it was desired to extirpate weeds and briars so that they should not sprout again, they must be cut down in the wane of the moon. For some allied notion it was the custom to cut trees for use as firewood in the wane of the moon, as the timber cured more soundly and was less apt to become soggy and sputtery. The latter is also a Scotch superstition, as there is a Lowland agricultural maxim, 'Cut wood when the moon is wadel,' the word 'wadel' meaning disappearing, diminishing or waning. Jacob Grimm, in his *Teutonic Mythology*, after bringing forward a mass of kindred superstitions, offers the general theory that, in folk-lore, operations requiring severance, dissolution, cutting down or removing from, promise best results if conducted in the wane of the moon; while those of an opposite character are appropriate to the new moon." Thus planting operations are best performed while the moon is waxing; but, in his natal region, says Dr. Brinton, "by some it was held that the sign varied with the nature of the crop to be planted. Root crops, such as Turnips, Potatoes, Carrots, and the like, which ripen their edible portions beneath the soil, should be planted in the wane of the moon, or, as the local expression was, in the 'sinking' sign, in contradistinction to the 'rising' signs, which were those of the increasing orb. Even such a matter as fence-building should be carried on with due respect to these potent influences. A fence should be constructed in the 'rising' signs, for if the posts be planted and the corner-stones which support the rails in a worm-fence be located in the 'sinking' signs, the former will rot more readily, and the latter will sink into the ground and allow the bottom rails to decay."

The community in which Dr. Brinton was brought up was by no means peculiar in this respect, for these same superstitions were prevalent in all the middle states, at least. In one agricultural community with which we are familiar, not fifty miles from this city, all the farm operations were made to conform with the supposed influence of the various phases of the moon, or, rather, of these phases in connection with the signs of the zodiac, so that the almanac was the ultimate authority in almost all matters of farm practice. Not only was it supposed that rail-fences were to be constructed at certain periods of the lunar month, but no one laid a stone wall in the "new of the moon," through the apprehension that the frost would heave it, and it was a matter of universal belief that if Lima or Pole Beans of any kind were planted in the "old of the moon" they would never climb or fasten themselves to the supports provided, but settle down in a tangled mass on the ground.

Notes.

There must be still a good many woodsmen at work in the forests of Michigan, since from Menominee alone 600,000,000 feet of lumber have been shipped this year.

About \$40,000,000 is paid every year in Germany for the creation and preservation of forests; 200,000 families are supported from them, while something like 3,000,000 find employment in the various wood industries of the empire. The total revenue from the forests amounts to \$14,500,000, and the current expenses are \$8,500,000.

Monsieur H. Correvon, Director of the Alpine Garden of Acclimatization at Geneva, who is doing so much to rescue Alpine plants from extinction, has issued the prospectus of a monograph on hardy Orchids. The work will be illustrated by numerous engravings and will be furnished at the low price of three and a half francs.

Last week we spoke of a new Chrysanthemum which received the prize as the best pink at the Philadelphia show under the name of Magnet. This name has already been given to one of Mr. W. K. Harris's seedlings, which was distributed by H. Waterer, and the new Chrysanthemum has therefore been named J. J. Cliffe.

The agricultural experiment stations of the various states published last year, in addition to their annual reports, 225 bulletins, which were mailed to 340,000 addressees. In this way 35,000,000 pages of reading-matter were distributed among the people of the country, and a great part of the same matter was still more widely spread by the newspapers which quoted it.

A touching old rural custom still prevails in the western parts of France during the harvest-season. On the edge of a field bordering the highway a sheaf of grain is left standing, to which all the peasants of the village contribute, and which is called "the stranger's sheaf," as it is the property of the first tramp or other homeless wayfarer who may care to carry it away and profit by its price.

One of the famous White Oaks of New Jersey stands in the Presbyterian churchyard at Basking Ridge. It measures fourteen feet four inches in circumference at five feet high, while the branches shade a circle 115 feet in diameter. It has been a famous tree for more than a century, and it was, no doubt, a noble specimen in 1730, when the log-church was built on the ground where the present one now stands.

Professor B. D. Halsted, of the New Jersey Agricultural College, has prepared samples of the seeds of one hundred species of American weeds in metal-capped vials, which are arranged in four rows of twenty-five each in a tray, each vial in its own pocket and with a printed label. On the inside of the tray is a label giving a list of the hundred weeds with their botanical and common names in the order of the families to which they belong. The usefulness of such a set of seeds ought to be evident, since by means of it the foul seed in commerce can be readily identified. The sets were particularly made up for experiment stations and seedsmen, and one of them is sold complete for \$10.00.

The oldest horticultural association in Europe is the Royal Society of Agriculture and Botany of Ghent, established in the year 1808. Its annual exhibitions are always of great interest, and every five years it holds international exhibitions, the thirteenth of which is announced to open on the 16th of April next and to close on the 23d of the same month. No less than 660 classes of exhibits have been determined upon, associated in twenty-six great groups; and the prizes will be of unusual value, chief among them being the Queen of Belgium's prize, a large gold medal, for "twenty-five different species of hot-house plants in flower," and the King of Belgium's prize, a similar medal, for "the most varied and meritorious collection of 100 exotic Orchids."

Monsieur Ledain, the director of an agricultural school in Brittany, has asserted that moles may be poisoned by means of live earthworms which have been sprinkled with nux vomica. The worms, he says, should be collected and left in peace for twenty-four hours to disgorge the earth they have swallowed. Then they should be put in a jar and sprinkled with the drug in the proportion of thirty grains to a saucerful of worms. Twelve hours later they will be ready for use; and then they should not be touched with the fingers, but taken up with little wooden pincers and put at the entrance of the mole-galleries, being covered with clods or bits of tile in order that the mole may not be alarmed either by a current of air or a ray of light.

The Proceedings of the Convention of the Society of American Florists last year, at Washington, have been published in an instructive pamphlet of 170 pages, of which about fifty are

taken up with a review of new plants. The plants mentioned are by no means new, many of them, indeed, having been well known for a long time. The value of the review lies in the fact that it is made up of contributions from several different men, each one of whom gives a list of the class of plants with which he is familiar. Each one, too, has named such plants as seemed to him worthy of mention, together with brief descriptions. Of course, these descriptions vary in merit and the lists vary in range, so that there is little unity in the review. Although it is not so valuable as it would have been if it had been edited or compiled by a single person, and upon a definite plan, it is yet very interesting and has considerable permanent value.

An English horticultural journal recently recommended, as a novel manner of ornamenting dinner-tables, that branchlets of Birch should be thoroughly wetted and then whitened by being thickly sprinkled with flour, that these should be grouped in a central pot, and that flowers treated in a similar way should be dispersed about on the table. *Le Jardin* and another French journal have quoted this advice with approval, saying that such snowy decoration must produce a very cool and pleasant effect, especially in hot weather. But to an unsophisticated transatlantic taste they sound almost as inartistic and quite as inexcusable as flowers dyed to an unnatural color. Surely foliage and blossoms encrusted with white paste cannot make a really beautiful effect, while in the hottest weather there can be nothing more cool and pleasant to the eye than arrangements of naturally white blossoms, or even of delicate sprays of green leafage, accompanied by no flowers at all.

About five tons of the seed of a yellow Onion are annually produced in the state of Oregon. The yield varies with the soil and season, and the presence or absence of mildew, which is the only disease, so far, to which the crop is subject there; but an acre will yield on an average 500 pounds. In harvesting, the heads are cut off separately and let fall into baskets, and when these are full they are emptied into sacks which are placed upright at suitable distances apart. When filled the sacks are conveyed to drying-sheds, and the heads are spread thinly on platforms that are raised above each other, six or seven high, where they remain for a week or two till nearly dry. They are then taken into the sunshine and spread on large cloths for a few hours, when they are ready for threshing. Threshing is usually done by barefooted horses on a tight floor, and the seed is winnowed out through a mill and afterward washed in clean water, so that the light seed can be skimmed off and removed. The heavy seed is then taken out of the water, dried quickly to prevent sprouting, fanned once more, and it is ready for market.

A recent number of the *Revue de l'Horticulture Belge* declares that at the exhibition of the Royal Agricultural and Botanical Society of Ghent, which was to open on the 13th of November, an interesting surprise would be presented to lovers of Chrysanthemums. "Inspired, it seems," says the writer, "by the example of processes in vogue in China, an amateur of Ghent, Monsieur Alexis Callier, has grafted Chrysanthemums on *Anthemis frutescens*, and the result he has attained is so extraordinary that this mode of culture will revolutionize the world of chrysanthemophiles. To-day we will simply cite a few facts, promising more detailed information after the exhibition opens. The variety Val d'Andorre, for instance, which was grafted in February, has attained a height of five feet eight inches, while its head is six feet eight inches in diameter and bears 380 budding shoots. An Etoile de Lyon, with a head five feet in diameter, shows 150 budding shoots. A variety with large white flowers, grown from seed by Monsieur Callier, measures about seven feet in height, and is likewise a mass of buds; and a Paul Fabre will carry not less than 300 of its bright red, brilliant blossoms. This variety was grafted in April."

Catalogues Received.

ORANGE JUDD Co., New York; Rural Books.—HARLAN P. KELSEY, Highlands Nursery, Linville, Mitchell County, N. C.; Wholesale offers of Native North American Ornamental Plants.—WM. PARRY, Parry, N. J.; Small Fruit Plants, Fruit, Nut and Ornamental Trees.—F. S. PHENIX, Bloomington, Ill.; The Lincoln Pear.—PITCHER & MANDA, The United States Nurseries, Short Hills, N. J.; Selected Novelties of Chrysanthemums.—REASONER BROTHERS, Royal Palm Nurseries, Oneco, Fla.; Tropical, Semi-tropical and Hardy Fruit and Ornamental Plants.—FREDERICK ROEMER, Quaedlinburg, Germany; Novelties in Flower Seed.—MRS. THEODOSIA B. SHEPHERD, Ventura-on-the-Sea, Cal.; Wholesale Trade List of New and Rare Seeds, Bulbs, Plants and Cacti.

The Defacement of Scenery.

A FEW days ago *The Tribune*, of this city, published a letter from a correspondent whose sensibilities had been outraged by the sight of a staring advertisement painted on the face of Storm King, on the Hudson. The writer desired to know whether there was no body organized for the purpose of stopping vandalism of this sort, and he was informed that no such association existed, although a law had been enacted in this state which made the defacement of scenery a misdemeanor, punished by fine or imprisonment. But laws, however stringent their provisions, are of very little avail unless they have strong public opinion behind them, and the great mass of our people do not seem to resent it as a personal injury when the natural beauty, which it is their right to enjoy, has been marred or obliterated to serve some private purpose. Not long since, within the limits of this city, and on grounds controlled by the Park Department, the rocks were covered with violent invitations to purchase somebody's stove polish and to swallow a particular kind of liver pill, and no protesting voice was heard. Our public highways and pleasure-grounds, as well as private places, are amply protected against invasions of this sort, but public officials and private owners rarely assert their rights. It is a misfortune that there are men who are willing to make every pleasing prospect hideous for the sake of advertising a nostrum in which they have a proprietary interest. It is a much more disagreeable fact that the public sentiment on this subject is so feeble that no effective protest is made against it.

The same number of *The Tribune* which contained the letter spoken of also contained a paragraph to the effect that the higher slopes of Greylock Mountain were being rapidly stripped of their forest-growth, and that the inhabitants of the surrounding region were distressed because the mountain views were thus robbed of their attractiveness. It was also stated that the portion of the mountain thus denuded was owned by some association and held as

park property. We know nothing of the facts of the case, but everybody knows that destruction of this sort is going on almost everywhere where there is a mountain or a forest, and that the men who are sweeping away these woods are turning scenes of beauty into scenes of desolation more rapidly and completely than this can be achieved with an advertiser's paint-pot. Now, it is not to be hoped that all our forests can be left standing to satisfy the æsthetic sentiment of a portion of the community. Lumber must be had from some source, and men who own timber-trees have a perfect right to sell them for economic use. At the same time it is undeniable that many places could be named where, even in a pecuniary sense, the trees are worth more to look at as they stand than they will be after they are sawed up into lumber. We have so often spoken of the money value of attractions of this sort that there is no need to enlarge upon the subject, but it may be added that there is no reason why certain forests should not be worked so as to yield the highest product possible and yet retain their beauty as portions of the landscape.

The simple truth is, that few persons ever think of natural beauty as a possession worth considering by "practical" men, much less as a public possession which it is a patriotic duty to preserve and transmit to posterity. Few persons look upon the natural landscape-beauty of the country as a factor in promoting mental and spiritual health, as well as a source of elevated pleasure. And yet it is strictly true that this is one of the functions of beautiful scenery, and if the people hold any inherited rights in blessings of this sort, the destruction of such beauty is a public offense akin to that of poisoning the free air or polluting the general water-supply. An occasional spasm of indignation against the advertiser's agent who irreverently lifts his hand against a few stones and fences may be an encouraging symptom, since it shows that there does exist among us a slumbering sense of the right of the people to the enjoyment of natural beauty. But, after all, the advertising-man is a petty offender when compared with many great corporations. What wealthy company was ever known to make the slightest effort to protect the scenery from unnecessary defacement in locating or constructing a railroad? What corporation ever takes thought to preserve the fair face of nature from needless scars when opening a mine or working a quarry or building a factory? How many lakes in the Adirondacks, and how many reservoirs elsewhere, are surrounded by a fringe of death, as the water has risen and drowned the roots of the trees on their banks, and who took any thought to prevent this hideous and depressing effect when the dam was built?

Of course, civilized man must have mines and quarries, reservoirs and railroads. Constructions of this sort necessitate some displacement of the elements of beauty in scenery; but they need not inflict frightful and incurable wounds, and if their owners and builders had a proper respect for the rights of others the defacement would in most cases be trivial. Works of this sort could often be made, under artistic direction, to beautify rather than disfigure the scenery, so that each generation would leave the earth to its successors a more attractive place for human habitation. Societies for preserving natural beauty have been formed in more than one European country, and they will be organized here with increasing enlightenment. They are needed for wider duties than the protection of the unparalleled grandeur of Niagara from vulgarization or the preservation of the forest-crown of conspicuous mountains like Greylock, or the rescue of Storm King from vandal hands. Their success must grow out of a general appreciation of the value of all scenes of natural beauty as a public possession. Is it too much to hope that the time will come when a wanton or needless destruction of the natural beauty of the world, which is our common heritage, will be treated as a gross offense against public decency, and when such an offense will be considered as truly a felony before the law as any other invasion of the natural rights of the people?

Llewellyn Park.

LEWELLYN PARK has an historical interest from the fact that it was the first attempt on a considerable scale to organize what has been called a "residence park"—that is, an area of ground which is treated as a unit from the landscape-gardener's point of view, and yet is divided up among various property-owners, each one of whom owns his plot, but under certain restrictions in regard to its relation to the whole. Llewellyn Park was admirably situated for an experiment of this sort, and it was conceived and planned by a man who had not only a passionate love for nature but also a genius for organization. This man was Mr. Llewellyn S. Haskell, who saw the possibilities offered by the south-eastern slope of the Orange Mountain, which is adjacent to the city of Orange, and from which the greater cities clustered around New York harbor can be seen, and almost heard, and yet contains passages of untamed beauty and sylvan picturesqueness which are most refreshing to city-wearied senses. Mr. Haskell began to secure land as long ago as 1853, and he soon had possession of six to seven hundred acres in one body, extending from the level at the base of the mountain to its summit. Some of the land was rugged, and some forest-clad, although the hard features of most of it had been softened by cultivation for many generations. The prospects toward the south and east are magnificent in their extent and variety, while the land itself was made unusually attractive by a sunny exposure, diversified surface and fertile soil.

This park was divided up, and sections of it sold to persons who wished to have homes amid country surroundings. The land was conveyed to each resident in fee-simple, but he was restrained from erecting factories or other structures offensive to his neighbors, and he was under obligations to contribute to the general maintenance of the park. Some ten miles of admirable roads, with bridges and other necessary constructions, were made. There are several entrances, the principal one being the subject of our illustration on page 583. The skill with which this has been designed and constructed is a fair sample of the quality of the work throughout the park. One of its most beautiful natural features is a ravine which traverses its entire width to the very summit of the mountain. Through this runs a happy little brook, and the land on both sides of it, amounting to some fifty acres altogether, is held as the common property of all the residents of the park, and is to be reserved for all time as a general pleasure-ground. To maintain this "Ramble," with the roads, road-borders, walls, bridges, etc., an annual tax of ten dollars is levied on each acre of land.

Mr. Haskell died before his plans were fully realized, and the park is not yet thoroughly occupied and improved. It is, however, a place of rare interest and beauty. It perhaps contains no primeval forest, but there were many stately trees here when Mr. Haskell obtained possession, trees more than a century old, and those which he planted have already attained sufficient size and age to give them dignity. In all parts of northern New Jersey the natural forest-growth is very rich in species, and examples of nearly all of the trees which are native in this vicinity are found within its boundaries. Oaks of several species, Chestnuts, Hickories, Maples, Tulip Poplars and Beeches, many of them trees of magnificent proportions, are especially abundant, and the extent of forest and thicket is still sufficient to invest the park with a woodland charm in spite of the many residences, more or less pretentious, within its borders. Indeed, the number of these buildings could perhaps be doubled without destroying its rural and sylvan beauty.

Llewellyn Park is old enough to have a history. Children who were born in it are now living there with families of their own, and there seems to have grown up such an attachment to the place among the residents as men only have for their homes. Their gratitude to Mr. Haskell

for his conception and its fulfillment has been expressed in the form of a bronze portrait-bust, erected in his honor near the entrance. It is easy to conceive that a community of persons who appreciate the advantages of such an arrangement and enter heartily into it might persistently adhere to its original purpose. If such a park was originally well planned, and if a competent superintendent, who sympathized with its aim, could be had to insure its maintenance, its beauty and usefulness would steadily grow as it matured toward the realization of its design, and it would be an ideal place of suburban residence. But as time passed new owners would have to be admitted to the circle—families with different tastes and preferences—so that at last it might be possible to have the park filled with people who cared only for that portion of the land which they owned, and took little interest and no pride in the scheme as a whole. Parks somewhat similar to this in character have been of late years established in various parts of the country, and it would be instructive to know something of the lines upon which they have developed and how nearly they are fulfilling the purposes of their founders. The problems in social science which are here presented are still more intricate than those in landscape-architecture, and we should be grateful to any reader who has had experience in the practical working of such organization for a statement of facts in the case.

Notes of a Summer Journey in Europe.—XIX.

A WEEK spent among the living collections at Kew, and devoted almost entirely to the woody plants outside, with scarcely a glance within the greenhouses, is hardly sufficient to gain an intimate knowledge of the rich stores in this botanical treasury; but with well-used time one may acquire some general idea of the place.

Kew is so often written about and described, and Mr. Watson and Mr. Nicholson have given us so many and such full accounts of current events there, that such matters call for no additional mention; but since it has just attained the jubilee, or semi-centennial, year of its efficient reorganization it is worth while, perhaps, to make a hasty sketch of its development.

The early history of Kew Gardens, a good résumé of which may be found in the *Kew Bulletin of Miscellaneous Information* for December, 1891, is interesting as showing how this, like so many other scientific and proven useful institutions, had to struggle through a long series of vicissitudes before its value was thoroughly appreciated by the public and it became properly established on a permanent basis. Until within about fifty years Kew may be considered to have been the private domain of the sovereign, although in the period immediately preceding its reorganization its strictly private character had been gradually diminishing, and it became more accessible to the public and more of a national charge. But even while it formed a part of the royal estates it was famous in the botanical world of the day, for it was under the superintendence of such men as the Aitons, and for a long time Sir Joseph Banks may be considered to have been the director in fact if not in name. The celebrated William Turner, who died in 1568, has left a record of having had a garden at Kew, but of this nothing is really known.

The beginning of a collection on the present famous site is said to have been made soon after the middle of the seventeenth century by Lord Capel, a brother of Lord Essex, who introduced a large number of kinds of trees and shrubs from France. Some of these were probably fruit-trees, and very likely some came from the famous "potager," or Royal Kitchen Garden, at Versailles, which was established at about the same time. In accounts published in the latter part of the seventeenth century we read of Capel's beautiful and well-kept orangery and myrtetum; his *Lentiscus*-trees, for which he paid £40; his trimly shaped white-striped *Hollies*, which cost him £5 each, and his flowery and showy *Laurestinuses* trimmed to equal regular size.

"About the year 1730, Frederick, Prince of Wales, obtained a long lease of Kew from the Capel family, soon after which he commenced a fresh arrangement of the pleasure-grounds, which were laid out, and additional plantations made, under the direction of the celebrated Kent, who was also engaged in the decoration of the house itself." This Prince of Wales died in 1751, and his wife, the Princess Augusta of Saxe Gotha, who died in 1772, is said to have given to Kew Gardens, during the

last years of her life, "the definitely scientific character which they have ever since retained." In 1761 a large hot-house, 110 feet long, was designed and erected by Sir Wm. Chambers, and it was at that time the largest in the country. It was taken down in 1861, or just one hundred years afterward.

After the death of the Princess Augusta Kew Palace and the grounds passed into the control of George III., who is credited with having strictly maintained the botanical character of the establishment which had been begun by his mother. About this time Sir Joseph Banks began to figure in affairs at Kew and his name to become familiar in botanical literature, and especially with regard to the introduction of many plants until then unknown to the science of botany or in cultivation. Largely owing to this gentleman's liberality with his time and money, the gardens soon took a leading place among all such institutions in Europe, and, although its standard appears to have varied in later years, Kew began to be looked upon as a Mecca by botanists and gardeners. The efficiency and eminence of such gardeners as the Aitons at Kew helped to make its treasures widely known and appreciated. William Aiton, in 1789, published his *Hortus Kewensis*, or catalogue of plants in the Royal Gardens at Kew, a work including some 5,500 species, a brief description of each, its native country, date of introduction and introducer being given.

In 1772 the first regular collector was sent out from Kew, the collector in question being Francis Masson, whose destination was the Cape of Good Hope, and who was instrumental in introducing hundreds of species, some of which were collected in other fields besides those of South Africa. From this time the treasures of numerous collectors found their way to Kew, and thence were distributed to other parts of the kingdom or to colonies abroad.

That portion of the grounds in which a collection of trees was established was at first quite small, only a few acres in extent, although some interesting trees were also planted outside of it. It is curious to note how some of these early-introduced plants were first treated, their character in regard to hardiness not being well understood. For instance, a fine specimen of the Japanese Ginkgo biloba was originally trained against a wall. One of the largest and best accessions to the collection of trees was obtained from the garden of the Duke of Argyle, at Whitton, in 1762 or 1763. These trees had been raised from seed many years before by the tree-loving Duke. They were transplanted to a part of the Kew grounds not now designated the Arboretum, but several of the specimens are still standing where they were placed 130 years ago.

The Arboretum proper, as it exists at present, includes about 178 acres, which, until within recent times, or, more precisely, until 1850, was simply a sort of pleasure-ground and game-preserve. Since that time it has been planted with trees and shrubs grouped with regard to botanical sequence according to modern classification. The comparatively small size of many of the exotic trees is likely to prove somewhat disappointing to those persons who have come to think of Kew Gardens, as a whole, as a very old institution. The fact is, that the territory has been acquired gradually. With new accessions of land and changes in the management, alterations and modifications of plans and planting have seemed necessary, in order to give the whole establishment a regularly arranged aspect instead of the heterogeneous aggregation which it otherwise would present for all time. As it is now probable that no material additions to the area will be made, or, at least, be absolutely necessary, the trees are likely to remain in their present positions and grow without further molestation.

Besides the 178 acres called the Arboretum, the Botanic Garden proper includes about seventy acres, so that the whole establishment at present comprises very nearly 250 acres, an area requiring a good deal of time to go over so as to thoroughly appreciate the collections planted upon it. The situation is not the most advantageous for the finest development of tree-growth, because the soil is mainly of a poor, sandy or gravelly character. But while there is a lack of natural fertility, a partial compensation may be found in an abundance of moisture, both in the general humidity of the atmosphere and the low-lying situation of a good portion of the ground, which is not very much above the high-water of the Thames, which bounds it on one side. Certain portions of the garden are said to have been formerly covered by ponds or lagoons, and the site of the large Palm-house was once covered by an extension of the same sheet of water which now lies in front of it.

Since its reorganization in 1841 Kew has successively been presided over by three directors: first, the late Sir W. J. Hooker, followed by Sir J. D. Hooker, and lastly, Mr. W. T. Thistleton Dyer, who has succeeded in the care within a few

years. The institution is supported by the Government by an annual appropriation, which nearly amounts to a hundred thousand dollars. After a certain number of years of faithful service the employees are entitled to retirement with a pension.

Kew has accomplished, and is accomplishing, four distinct and valuable objects. It is acknowledged by all the world as the headquarters of botanical science; it has been and is a centre of economic botany, by which the colonies in all parts of the globe have especially benefited; it is practically a great school of botany and horticulture, where instruction is given in all matters relating to plant-life, both on its useful and æsthetic side, and it is a place of rest and quiet to hundreds of thousands who visit it every year.

Arnold Arboretum.

J. G. Jack.

Botanical Notes from Texas.

WACO is in central Texas, just at the ninety-first meridian, and in latitude about 31° 20'. The city is in the valley of the Brazos River, which, though nearly a thousand miles long, is entirely within the limits of Texas. The city takes its name from the Waco Indians. Here their principal chief resided, and here their council-fires were lighted.

About three miles above the city, on the right bank of Bosque River, a little above its junction with the Brazos, there is a high bluff. A projecting point of the bluff is known locally as Lovers' Leap, in accordance with the same old legend which has done duty in connection with many other precipitous places throughout the country; a daughter of the Wacos and her chosen warrior ended their lives and loves when hotly pursued.

Waco is a city of about 20,000 inhabitants. It is chiefly remarkable for the number and character of its artesian wells. Within the city or near it there are twenty-one of these wells, having an average depth of a little more than 1,800 feet, and a flow of from 100,000 to 1,200,000 gallons of water in a day of twenty-four hours, with a pressure at the ground of fifty pounds. The water of these wells, as it flows from the ground, has an average temperature of about 103°.

There have been a few light frosts here, and Cotton-plants are killed; but the gardens are still adorned with the choicest of Roses and Chrysanthemums. Leaves of Elms and of Box Elder and Hackberry are falling, while those of deciduous Oaks and Cottonwood and other species are taking on their handsomest autumnal tints, and in striking contrast with the unscathed bright green leaves of the Live Oak. Dripping Springs is on the left bank of the Brazos, about four miles above the city. For a long distance water continually drips from the rocks of the bluff about as it drips from the eaves of a building during a heavy rainfall. The handsome *Adiantum Capillus-Veneris* is there, pendent in great profusion from the rocks amid the falling drops of water. This almost cosmopolitan Fern is very abundant throughout central Texas; it fringes most of the irrigating ditches at San Antonio, and large and beautiful individuals crowd each other upon the moist rocks along Colorado River at Austin.

Hackberry is the most common street and lawn tree of Waco. I have noticed that "northers" have a killing effect upon China trees, even in this latitude, as the dead tops of many of them show. The drupes of this species are poisonous, at least to birds. Robins often eat them until they become intoxicated and tumble from the trees.

Several species of Aster are yet in blossom, with an occasional *Helenium*, and rarely the handsome flowers of *Gilia coronopifolia* are to be seen. *Centaurea Americana* is so abundant in many localities in central Texas as to become a weed. It is often seen in gardens, where its beauty entitles it to be. It extends northward throughout the Indian Territory.

Several species of *Desmanthus* abound in this region, among them *D. leptolobus*. This species extends northward in Kansas to the Saline River, or to beyond the thirty-ninth parallel. In early spring hill-sides here are covered with such eastern species as *Erythronium albidum*, *Anemone decapetala* and others, which mingle their beauty with the western *Lupinus subcarnosus* and many more decidedly western species. Our little *Dichondea repens*, too, is here. *Heteranthera graminifolia* is common in running waters of central Texas. It is very abundant in Colorado River at Austin. I saw it also in Llano River near Llano. This rather pretty aquatic has a more western range than is usually allowed it. I have collected it near the one-hundredth meridian in Kansas, and it probably extends still farther westward in this state.

Waco is the most northern station at which I have seen *Capiscum baccatum*, "Chiltapin" of Mexicans, growing without cultivation. The intensely acrid berries of this species are exten-

sively used by Mexicans as a condiment. That fact might excite no surprise. But birds are fond of them. Even mocking-birds eat them with avidity, and without injury to their vocal organs. Wild turkeys, too, use them in the fall, until they are literally seasoned by them, affording us most excellent natural "Chile con carne."

Acacia Farnesiana is rarely seen here, though it is one of the commonest shrubs or trees of southern Texas. It extends into the other Gulf states and far southward. So far as the observation of the writer has extended, this species attains a larger size than any other Texas species of the genus. I saw a tree of this species felled last summer in Victoria that was about eighteen inches in diameter and thirty feet or more tall. It is a handsome sight in blossom, covered with thousands of little globes of small, very fragrant, yellow flowers. About the first of last January, at Goliad, I saw such a tree in full blossom. *Apostaxis* occurs largely in this species, as it does in most of its congeners, and also in Mesquit. These gums possess, probably, properties similar to those of gum Arabic, for which they may prove to be a valuable succedaneum.

Parkinsonia aculeata, "Ratama," or Jerusalem Thorn, is also here in gardens and as an escape. Its light graceful sprays and foliage and handsome yellow flowers, which are produced from May to November, make it a popular lawn tree throughout the south and as far north as it will thrive. *Diospyros Texana*, Black Persimmon, or "Chapate," grows on the bluff at Lovers' Leap. The species is very abundant from this meridian far westward. It may be seen, sometimes, not more than three or four feet tall, profusely covered with its small black fruit, and through all degrees of height, until it becomes a tree of middling size. The largest individuals that I have seen were on the bluffs of the Arroya near Beeville. Those were at least a foot in diameter and thirty-five feet tall. The fruit of this species is sweet and less astringent than that of its more northern congener, but it, pulp and all, is so intensely black, that in eating it the lips and fingers become of such a black-inky hue that it is not so generally eaten as the fruit of our other species, which also is found in this vicinity. The wood of *D. Texana* is very hard and close-grained and of economic value when such qualities are required of wood. Professor Sargent tells us that for engravers' blocks it is the best American substitute for box-wood. The bark of this tree exfoliates, and, when unleaved, the tree closely simulates in size, height and habit the cultivated Crape Myrtle (*Lagerstroemia*) when that plant is defoliated. The leaves of this species are small, oblong, thick, and with recurved margins. In the southern part of its range they persist until crowded off by the new growth.

Berberis trifoliolata, Currant, "Agrita," is one of the most interesting and important shrubs of western Texas. This Barberry is rarely found so far eastward, but I saw a few individuals on the bluffs of the Bosque. In southern Texas it blossoms as early as February and ripens its red fruit in May. The fruit, about as large as currants, has an agreeably acid flavor and is largely used for pies, jellies and preserves. The shrub may be easily recognized, even when destitute of flowers or fruit, by its glaucous evergreen leaves, which are variously cut and armed with spines. Its cultivation on an extended scale is desirable, as western Texas has no other early spring fruit which, green or ripe, will fill the place of this one.

Sophora secundiflora is rarely met with at Lovers' Leap, becoming very common farther westward. Usually a shrub, it occasionally becomes a respectable tree. Differing largely from our other native species, it produces large violet-colored flowers which are succeeded by large, often constricted, woody pods, each containing from one to half a dozen red, roundish, large seeds, which are said to be very poisonous. I have made no experiments to ascertain the truth of this charge. The seeds are easily polished, and are then quite handsome. Devout Mexicans use them in making the bead-rolls by which they tally their prayers. Growing with *S. secundiflora* sometimes, but oftener along streams in central Texas, is *S. tomentosa*. It is a small tree, with green bark, yellow flowers and small moniliform pods in lavish profusion. The seeds are blackish, small, and embedded in pulp. The eating of a portion of the pulpy fruit did not kill the writer.

Bumelia lycioides is abundant throughout this region. Its black oblong drupes are edible. The largest trees of this species that I have met were near Caldwell, Kansas. They were forty feet tall or more and a foot in diameter. The West Indian *Cassia occidentalis* is common in the streets of Waco. The odd *Eryngium Leavenworthii* is almost everywhere among limestone-rocks. This species is often mistaken by botanical tyros, sometimes for a Teasel, oftener for some *Cnicus*. Our species extends through the Indian Territory to Kaw River, in Kansas. When about to celebrate the nuptials of its flowers,

the whole plant shares in the festivities of the occasion, and, laying aside its plain green gown, attires itself in royal purple.

Cucumis anguria, which yields the gherkin of commerce, is often seen wild in this state. The fruit might be raised here without limit. The wild grapes would furnish the vinegar, Chiltapins the peppers, and Texas might supply the world with pickled gherkins.

Waco, Texas.

E. N. Plank.

New or Little-known Plants.

Prunus tomentosa.

THIS little Cherry has been introduced into cultivation at several widely separated stations in North America, and in the coldest region where it has yet been tried it appears to be quite hardy and vigorous. It has flowered and fruited for some years at the Arnold Arboretum; and on the grounds of the Iowa Agricultural College at Ames it is reported as withstanding perfectly the rigorous winters, its fruit-buds being hardy and its flowers enduring quite severe frosts without injury.

The species is a shrub and never attains anything like tree-form. Apparently mature plants at the Arnold Arboretum are only six or eight feet high, while it is described in accounts of it in its native habitat as from five to ten feet in height. It forms a broad, spreading, twiggy bush of numerous stems rising from the ground and clothed with branches to the base. These lower branches, where they touch moist ground, often send out roots and form independent plants. The bark is a gray or bronzy brown, at first comparatively smooth, but finally scaling off laterally in very thin flakes, like the bark of Yellow Birch.

The downy gray young branches are usually thickly covered with buds, from which a profusion of flowers and leaves appear simultaneously in early spring. In this latitude the blossoms begin to open soon after the middle of April, and they may be counted in best condition about the first week of May. They are smaller than the flowers of the common Cherry, white or light rose colored, usually assuming a distinctly rosy tinge before falling away. They are sessile, or almost so, and are crowded in clusters in the axils of the leaves. The leaves are mostly from one and a half to two inches long, rounded ovate in outline, acuminate, serrate, the serrations being tipped with a sharp point or mucro. They are sparingly hairy on the upper surface and densely and softly hairy beneath. The leaf-stalks are very short, and at the base of each is a pair of slender, lacinate, long, persistent stipules.

When ripe, the cherries average about half an inch in diameter, being round, or somewhat longer than broad. They are slightly covered with very short and inconspicuous hairs, and contain a medium-sized stone. They begin to ripen or change to a light red color in the latter part of June. Later the color becomes darker, and the cherries can hardly be considered to have attained their finest flavor and condition of ripeness until the second week of July. They have a pleasant slightly acid flavor; the flesh is firm and juicy, and without the noticeable staining properties characteristic of some wild cherries and plums. With careful selection and cultivation this little Cherry might prove of some economic value.

Prunus tomentosa is a native of northern China, and the same, or a closely allied, species is found in the high Himalayas of north-western India and in Thibet. It has been described by some botanists under the name of *P. trichocarpa*, or hairy-fruited Cherry, and plants labeled *P. mollis* have been received at the Arboretum.

The illustration on page 581 of a fruiting branch is of natural size, from a specimen grown in the Arboretum the past summer. The seed of this plant was collected in the mountains in the vicinity of Pekin, China, by Dr. E. Bretschneider, and was sown in March, 1884. It flowered and fruited in 1888, or earlier, and the bush now has apparently reached its fullest development, although it may attain a little larger size.

Arnold Arboretum.

Foreign Correspondence. London Letter.

A HANDBOOK OF IRIDEÆ.—This is the fourth of the valuable series of handbooks prepared by Mr. Baker, of Kew, and published in the last four years. No botanist of modern times has contributed more to what may be termed

garden botany than Mr. Baker, who has always shown a warm sympathy with and interest in horticulture, especially in its relations to systematic botany.

Since Herbert published his great work, *Amaryllidaceæ*, we have not had any book of more value to horticulturists than Mr. Baker's *Handbook of Amaryllidaceæ*, published in 1888. In the following year came a similar work devoted

to Bromeliaceæ, a most useful book to the few who are interested in these beautiful but hitherto neglected plants. Uniform with these two is the *Handbook of the Fern Allies*, as Lycopodiums, Selaginellas, Equisetums, and the like, and now we have this book, which is devoted to the Iris family. Mr. Baker says it is the last of the series, and that they are the outcome of special attention to their respective subjects since 1866, when he first joined the herbarium staff at Kew, of which he is now the head.

The sister order, Liliaceæ, he dealt with in an exhaustive series of papers published in the Journal of the Linnæan Society, but I feel certain that I speak for a large number of horticulturists in urging upon Mr. Baker the need of a similar work on Liliaceæ to those which he has now produced on Irids, Amaryllids and Bromeliads.

In the classification of the genera and species Mr. Baker has followed the *Genera Plantarum* of Bentham and Hooker with very slight exception.

Iris is limited to 161 species found in the North Temperate Zone, the South African *Moræas* being still retained as a distinct genus, although there does not appear any good reason for keeping them separate from Iris other than their geographical position. The great "Iris" from Lord Howe's Island, figured in GARDEN AND FOREST (vol. iv., p. 355), he places along with the *Moræas*. *Viesseuxia* and *Dietes* are also sunk under this genus.

There are no less than 133 species of Iris with rhizomatous stems, the remaining twenty-eight species being bulbous. Of the section *Oncocyclus* twelve species are described, most of which are in cultivation. The beautiful *I. Susiana*, *I. Gatesii*, *I. Sari* and *I. Iberica* belong to this section, all of them remarkable for the large size and great beauty of their flowers, and perhaps no less remarkable for their refractory behavior under cultivation.

MORÆA has fifty-four species. These lovely flowered, easily cultivated plants are not so much cultivated as they deserve to be. We have few more charming flowers than those of the plants hitherto known as *Viesseuxias*, and almost as much may be said of many of the *Moræas* proper. *M. Robinsoniana* is one of the handsomest plants in the whole order.

MARICA is a genus of stove-plants as easily grown as *Aspidistra* and nearly as useful for its foliage effect. At Kew we find the several species of the greatest service in the large houses, their evergreen, dark flag-like leaves always looking healthy, and their habit of producing suckers in abundance rendering them serviceable for planting in the beds or for borders. Mr. Baker describes eleven species, of which the best in cultivation at Kew are *M. cœrulea*, *M. Northiana* and *M. gracilis*.

TIGRIDIA is allowed eight species, of which the best is *T. Pavonia*, though some of those which are not known in gardens, for instance, *T. Dugesii* and *T. buccifera*, are likely garden plants, from the description of them. There does not appear to be any good reason for keeping up *T. Pringlei* as a species distinct from *T. Pavonia*.

Crocus had already a splendid illustrated monograph by Mr. G. Maw, F. R. S., but it is too expensive for the garden library. Mr. Baker divides the sixty-six species into three sections, which are again divided into spring and autumn flowering groups. Those who are only acquainted with the ordinary garden *Croci*, which flower in the spring, will be surprised to learn that of the true species no less than forty-two flower in the autumn, twenty-four only flowering in the early months of the year. *C. Susianus*, from the Crimea, is the "Cloth of Gold *Crocus*" of gardens; *C. Mæsiacus*, or *luteus*, is the well-known Dutch *Crocus*, and *C. biflorus*, the Scotch *Crocus*. *C. versicolor*, from the mountains of southern France, is the purplish feathered *Crocus* so common among spring bulbs, and *C. vernus* is the parent of the cultivated lilac and white varieties. Mr. Baker places *C. obovatus*, the Neapolitan *Crocus*, as a variety of *C. vernus*. I have before given a list in GARDEN AND FOREST of the best of the autumn-flowering species, but I would recommend Mr. Baker's book to any

cultivator who wishes to take in hand these beautiful and most useful species with a view to breeding from them a race of as great value in autumn as are the common spring-flowering kinds, a very possible and certainly most desirable object.

ROMULEA has thirty-three species, among them being some very pretty *Crocus*-like summer-flowering plants such as *R. bulbocodium*, *R. Clusiana* and *R. rosea*, grown in quantity by the Dutch bulb nurserymen. There are eighteen species of the Australian genus *Patersonia*, which is represented in a few gardens by *P. longiscapa* and *P. sericea*, plants worthy of a place in many gardens. The same remark applies to *Aristea*, of which there are twenty-seven species, including the pretty blue-flowered *A. corymbosa*, generally known in gardens under *Witsenia*.

THE *IXIAS* are allowed twenty-four species, but they cross so freely, even in a wild state, that it must be very difficult to draw the line between one species and another, as, indeed, is intimated by Mr. Baker. *Freesia* is limited to one species with two varieties, *alba* and *odorata*.

WATSONIA, a genus quite as worthy the attention of cultivators and breeders as its ally, the *Gladiolus*, is composed of fifteen species, nearly every one of which is cultivated at Kew. There are few more beautiful bulbous plants than *W. angusta* (in flower now), *W. Meriana* and its varieties, *W. coccinea*, *W. densiflora*, *W. rosea* and *W. marginata*. They are as easily cultivated as the common *Gladioli*, and they flower freely and continuously. There are twenty-seven species of *Babiana*, all African; seventeen species of *Acidanthera*, of which, so far as I know, the handsome *A. bicolor*, figured in GARDEN AND FOREST (vol. i., pp. 486, 487) is the only one in cultivation. They, too, are all African.

CROCOSMA AUREA is the accepted name for the plant known as *Tritonia aurea*, while of *Tritonia* proper there are thirty-one species, included in which is the plant known in gardens as *Montbretia Pottsii*, the parent with the *Crocus* of a race of most beautiful and easily grown hardy bulbs, which we owe chiefly to Monsieur Lemoine, of Nancy.

GLADIOLUS comprises no less than 132 species, fifteen of them natives of Europe and western Asia, all the others being African. Of the latter there are fifty-seven species with linear or rush-like foliage, and thirty-seven with ensiform leaves. Comparatively few of these have been introduced into gardens, although many of those not yet tried are evidently worth looking after, and they are generally natives of easily accessible places. Mr. Baker gives the following as the principal of those bred for garden-plants: *G. psittacinus* (*Natalensis*), *G. cardinalis*, *G. oppositiflorus*, *G. blandus*, *G. tristis*, *G. purpureo-auratus* and *G. Saundersii*. From these seven species have been obtained the four distinct races of *Gladioli*, the *Colevillei*, *Gandavensis*, *Lemoinei* and *Nanceianus* sections.

I have purposely gone into detail that the attention of readers interested, or wishing to be interested, in bulbous plants may obtain some idea of the interesting character of the Order *Irideæ* and of the way it has been dealt with by Mr. Baker. The whole of the work is in English; good plain English, I might say. The book is published by G. Bell & Son, London and New York.

ZONAL PELARGONIUMS.—American growers of so-called *Geraniums* may be interested by an account of the way these plants are treated by our best English growers who want them for winter effect. The *Geranium*, as this section of *Pelargonium* is popularly named, is emphatically everybody's plant. It will live and grow and flower under the most indifferent treatment, but, like all plants of this nature, it pays for good cultivation. There are not many growers in England who can produce such fine plants, large trusses and large well-colored flowers of *Geraniums* as Mr. Cannell, of Swanley. Mr. Pearson, of Chilwell, Nottingham, is, perhaps, as clever with them, and the Right Hon. Joseph Chamberlain is a very successful amateur-grower. Mr. Cannell has shown trusses almost as large as a child's head, composed of flowers nearly two inches in diameter. The Messrs. Pearson have long been specially interested in

Geraniums, both as breeders and growers, some of the best of the most popular kinds having originated in their Chiltern nurseries. Mr. C. Pearson was invited by the Royal Horticultural Society to lecture on the cultivation of Zonal Pelargoniums for winter, and the following is a résumé of what he said: People who object to the "glare" of the scarlet Geranium in summer delight in its warmth of color in December and January. The flowers are always useful, but specially so in winter, and they may be made to hold their petals a long time by dropping a little florists' gum in the eye of each flower. This gum is easily made by dissolving a little gum shellac in spirits of wine until the mixture is just thick enough to drop freely from a pointed stick. Dark crimson-flowered varieties, such as Henry Jacobi, are not the best colors for winter, as in sunless weather the flowers are often changed in color to a dull magenta. The best of the crimson-flowered kinds for winter is Charles Smith.

The following is my selection of the best sorts for winter-

and all flower-buds picked out as fast as they appear. The leaves should be thinned out severely. No stimulants, such as manure, should be given to these plants. In autumn the plants must be placed under cover, as they are easily spoiled by excessive wet. They should be allowed plenty of light and air, and, if necessary, more leaves be removed as well as the flower-buds.

A low span-roofed house, in which the stages are close to the glass and with a sunny aspect, is desirable for these plants during winter. The atmosphere in the house should be kept fairly dry by means of the pipes and ventilation. The temperature ought not to fall below fifty degrees in the coldest weather, and on mild nights it may be kept five degrees higher. During sunshine a temperature of sixty to sixty-five, or even seventy degrees, is not too high.

The plants should be watered in the morning. For the production of large trusses of flowers the point of the shoot must be stopped just above the bud. It is always best to stop the shoots after the flower-buds show.

Fig. 100.—Main Entrance to Llewellyn Park, West Orange, New Jersey.—See page 578.

flowering: White—Queen of Whites, White Lady, Sir Percivale. Blush White—Stella Massey. Pink—Constance, Lady Brook, Ethel Lewis, Amphion. Rose—Beauty of Kent, Rosy Morn, Rev. R. D. Harries, Radha. Salmon—Madame de Bourdeville, Ayesha, Lady Chesterfield, Mrs. Norman. Scarlet—Sunbeam, Swanley Gem, Corsair, J. L. Baldwin, S. Hibberd. Crimson—C. Smith, Nelly Thomas, T. Hayes. This selection may be useful as a guide to those who wish to grow a collection of the best sorts known in England.

The cuttings should be planted in August, and potted as soon as rooted into large thumb-pots, and again into four-inch pots. By the beginning of June they should be put into six or seven inch pots. The plants should then be placed outside in a sunny position, and, if possible, on a thick bed of ashes. All through the summer the plants should be carefully watered, the strong shoots checked by pinching,

The soil used is light loam, with a little cow-manure and sand. Leaf-mold is, Mr. Pearson believes, detrimental to good cultivation.

The Cherries of North-eastern Europe.

THERE is no more fascinating study to the lover of horticulture than that of the unfamiliar fruits of foreign countries which prove themselves to be particularly adapted to his own country. For upward of twenty years I have been engaged in this study, partly from necessity, because I am too far north and high up to grow the familiar varieties of my youth, but also because I find a real superiority, as well as a greater adaptability, in these novelties over the older sorts with which I had worked for years. While their work among the Apples of north-eastern Europe seems to me of far-reaching importance

to a broad region in northern America east of the Rocky Mountains, Messrs. Budd and Gibb, during their summer's tour in Russia some ten years since, did not neglect other tree-fruits, and a large variety of both Plums and Cherries were imported. Professor Budd's relations, then formed with careful and well-trained pomologists of that region, have resulted in a continuous influx of new varieties. In addition to these he has, by the aid of missionaries in northern China and Mongolia, secured many valuable varieties, and perhaps species, of the tree-fruits of that part of the world. Since then, through his kind aid, I have been enabled to grow and test on my own grounds a large variety of new tree-fruits, the study of which from year to year has occupied much of my time. I am convinced that these interesting researches, while perhaps not bringing quite so much of absolute and striking novelty before us as those of Professor Georgeson, in Japan, are yet of no less importance to the fruit-growers of our continent.

It may be well here to note that while Messrs. Budd and Gibb were for America the pioneer students among the orchards and gardens of eastern Europe, the fruits of that region were by no means unknown in other parts of Europe. The Russian Apples, Pears, Plums and Cherries are quite well known and distributed in north Germany and the Scandinavian countries. It was, indeed, by the way of Sweden, through England, that our earliest importation of Russian Apples took place some half-century ago. It is altogether probable that had not some enterprising fruit-growers of eastern Massachusetts imported that half-dozen varieties of Russian Apples we of the cold north might yet be left to our own extremely limited resources in the way of available tree-fruits.

As to Apples and Pears, I have endeavored to keep the readers of GARDEN AND FOREST informed of the progress which is being made in their study in northern New England. More recently I have been enabled to report something of parallel experiments with Plums and Cherries, and even in a slight degree with Apricots. Of this latter fruit, though the results with the Russian forms are not promising for northern New England, they have at least proved that there can be hardier races than those of western Europe; while later tests with sorts from Mongolia give strong hope that the area of their successful cultivation can be extended quite to the banks of the St. Lawrence River.

As already stated, north-western Europe is not unfamiliar with the native tree-fruits of Russia. Many of the Cherries recently imported into this country from Russia are grown now in Prussia, Poland and North Silesia. Yet their original home was, with slight doubt, eastern Europe and northern Asia. Some of these have even reached western Europe from Asia by the Cape of Good Hope, having been brought from Asiatic ports in Spanish and Portuguese ships. These varieties from both directions have met, and been found to be identical, in the gardens of Holland, for this is a small world after all. But the same or very similar varieties are reported as growing in a semi-wild state as escapes from gardens on all the bluff lands near the rivers of central Russia, while the most truly iron-clad, like the true Ostheim and the Besarabian, are strictly Russian. Other so-called Ostheims—no doubt seedlings grown from mixed seed in Germany, are not hardy, or at least not "iron-clad." And as to the now pretty well-known Griotte du Nord, it will be seen by a reference to the Pomological Manual of the late W. R. Prince, pp. 146, that "the Dutch obtained this variety from Russia." Indeed, as Professor Budd remarks, it is a variety of the Ratifa family, found growing with the Brusseler Braune, on most of the roadsides of southern Russia. These are not, like many of the Russian Cherries, a dwarf family; for Professor Budd says that on the road-sides and division lines of estates in Russia he has seen the trees much larger than he has ever seen Early Richmond, or any of the Montmorencys, in this country. In Iowa, and, so far as they have fruited, here in Vermont, they prove to be great and continuous bearers, even in the most unfavorable seasons. I have fine trees of these sorts, nearly twenty feet high, which have proved quite as hardy as our wild Bird Cherry (*Prunus Pennsylvanica*). They are chiefly valuable for culinary uses, canning, and the making of "Ratiña," or what is commonly known as "Cherry Bounce." Still, the slight bitter which characterizes this family of Cherries, even when fully ripe, is agreeable to many; and some regard them as excellent dessert fruit. Even when gathered prematurely, no trace of bitterness remains after cooking. Professor Budd expresses the belief that in time these iron-clad Ratifa Cherries will be planted along the roadsides in America, as they are in Europe.

Another variety, known as Lutovka, represents a family of large-growing road-side trees, found all over south Russia.

Where in the orchard such dwarfs as the little Spate Amarelle, Shadow Amarelle and Orloff, only six feet high, are seen in full fruit, Lutovka is at the same age a large round-topped tree. Its fruit exceeds the English Morello in size, is yellowish red in color, and would be called excellent for dessert use, even where the Heart Cherries can be grown. This family is so common in Russia that it is found as an escape from culture, yet it is only lately attracting the very favorable attention of growers in Poland, Bohemia and parts of north Germany.

The Asiatic Sweet Cherries, represented by Orel Sweet, are also strong growers, but not so upright as the Sweet Cherries of western Europe. A glance over the collection planted in 1883 in the grounds of the Iowa Agricultural College shows many varieties larger and stronger in growth than Richmond or Montmorency Ordinaire.

Of the dwarf sorts belonging strictly to Russia it is said that Orloff and Sklanka are proving continuous and heavy bearers. In my own grounds little trees three years set are bearing well, without regard for spring frosts in blooming time, and they mature their fruit as early as the Richmond. Sklanka is larger than Richmond, with a small pit, firm flesh, and is excellent for any use. Spate Amarelle, Shadow Amarelle, Large Long Late, Shubianka and Double Natle are continuous heavy bearers. Of some of these I have quite large trees, entirely unharmed by a cold that freezes mercury. There is no better fruit of this class for canning or preserving in sugar. They are incomparably better in quality for the table than any of the Morellos of western Europe; but as they are long in ripening, and double their size after beginning to color, their long exposure renders it necessary to protect the crop from birds by the use of netting. When fully black they are, to my taste, better than any of the Heart Cherries. Allow me to add that I am not propagating these fruits for sale.

Newport, Vt.

T. H. Hoskins.

Winter Protection.

IN almost every garden there is sure to accumulate a number of plants which one comes to consider indispensable, though not hardy enough to be left outdoors during the winter in severe climates. The cellars of dwelling-houses are not always available for storage, being either too hot or too cold, and the question naturally occurs, What are we to do with them? It is not advisable to place such plants in a heated structure, as they need rest, and should not start to grow until they can be safely planted outdoors in spring. The one place of all others for all half-tender border-plants is the cold-frame, but the term is perhaps an unhappy one, in that we do not build a frame and invite the cold to enter in because it is a cold frame; on the contrary, the frames are well protected in winter by a lining of dry leaves, packed tight outside and kept in place by boards, and the sashes are covered with mats, and shutters to keep the mats dry. In this way we manage to keep out the frost, and rarely do we get the plants frozen. Lily-of-the-Valley for forcing, Astilbe, pot Roses, Freesias, Ixias, Ranunculus, double Anemones, Anemone fulgens, Pansies, stock-plants of Chrysanthemums, Violets, Hollyhocks, Fox-gloves, Narcissi, Bulbocodiums, and, in fact, the whole of the winter-forcing bulbs may be safely stored in cold frames of this description. Chrysanthemums stored in this way produce excellent cuttings, stout and vigorous in May, just when they are wanted for growing on for pot-plants of medium size, or for large flowers. Freesias may be kept until March in this way, and will not have the weak habit of those brought on earlier in heat. All plants that have green tops must be exposed to the light on all favorable days and given air during sunshine, but bulbs and plants that have no top-growth may remain covered until required for use elsewhere.

There is a good deal of labor incidental to the management of cold frames in the covering up and uncovering daily, but this is offset by the little attention necessary in watering as in a greenhouse. Very little water is required in winter; the less the better, as long as the plants do not suffer, as one's greatest enemy is the tendency of such plants as Violets to damp-off; these must be carefully watched and decaying parts removed at once, or the plants will surely and rapidly die.

In the spring-time these frames can be utilized as hot-beds for the production of early vegetables, such as Cauliflower, Lettuce, Radishes, Beets and the raising of a host of tender seeds, such as Tomatoes, Celery, Zinnias, Asters, Stocks and many others. The use of the hot-bed was much better understood in the old days than it is now, but it is still the best of all ways to raise seeds and to grow on the young plants in a sturdy, vigorous way. We take out the soil to the required depth and place bricks under the corners of the frames to pre-

vent their settling down, and fill in with the fermenting material, covering this with soil about six inches deep. When the Lettuce-plants are set out Radishes are sown between the rows, and as the Lettuce is used from alternate rows, Cauliflowers are set in their places. Beets take long to mature, and are given a frame to themselves. In a word, there is no end to the ways in which cold frames can be utilized. We have sixty sashes, six by three feet each, all arranged on frames, three sashes on each. In this way they are easily moved from one place to another, and winter and summer these frames are always fully occupied. Mice are sometimes to be found with snug winter quarters in the bulb-frames, and a happy time they have until *Felis domesticus* comes on the scene. The moral is, examine the frames regularly, even if they are not opened daily.

South Lancaster, Mass.

E. O. Orpet.

Flowers in the Conservatory.

DECEMBER is a "between time" and usually the dullest month of the year in the conservatory. The *Chrysanthemum* is gone, and the usual array of Dutch bulbs, forced roots and shrubs are yet to come. *Freesia refracta alba*, with its graceful cymose-scapes of lovely, sweet-scented tubular flowers, is at this time very common. It is one of the most useful bulbs to grow for any purpose, and competes for popular appreciation with the better-known Roman Hyacinths and Narcissus. Cyclamens, which were formerly not considered in season until spring, may be had in bloom early by a little forcing. *Reinwardtia trigynia*, a bright yellow sub-shrub belonging to the Flax family, is quite ornamental at this season, yellow being rather an unusual winter color.

The indispensable Jerusalem Cherry (*Capsicum capsicatum*) is serviceable, as it bears a great deal of hard treatment. Species, varieties and hybrids of *Hippeastrums* are among the rarest and most beautiful of winter-flowering bulbs. Like most South American *Amaryllidaceæ*, they have a short season of growth and a long rest. One secret of success with these plants is, that they need quite a hot dry season of ripening to get them to bloom well. Dr. Masters is one of the earliest and best of the hybrids, many of which, unfortunately, are held at high prices. There are, however, a few of the types, notably *H. equestre*, *H. Johnsoni*, *H. psittacinum* and *H. vittata*, which are reasonably cheap and handsome enough for any one. *Hippeastrums* will bloom well for several seasons in one pot, provided a little fertilizer be given during their growing season.

The practice of growing *Mignonette* in pots for winter use is not carried to such perfection in this country as in England. Without the care necessary to grow specimens, a few plants in six-inch pots, carrying five to six spikes of flowers, will remain in bloom a long time, giving a continuous, delicate and agreeable odor. *Lachenalias* are coming along; why they are so seldom grown is a mystery, unless it be the exorbitant prices asked for some of the kinds, as *L. Nelsoni*. *Lachenalias* are very easy to grow, and multiply rapidly if given generous treatment. Last spring I bought three packets of seed at twenty-five cents each, and have now over three hundred seedlings, several of which, I noticed the other day, are showing flowering spikes; next year they will be flowering bulbs.

At Mr. H. H. Hunnewell's place I noticed a neat little *Polyantha Rose*, named *Mathilde Soupert*, nicely in bloom in a cold frame. During the winter, when cultivating cuttings of *Mignonette* and *White Pet*, varieties of this class, I was struck with their free-flowering qualities; small plants grew and bloomed on every inch of growth, and I have often thought since that they might be effectively used for the decoration of conservatories in winter.

Statice Halfordii is an uncommon tender Thrift, bearing large compound panicles of bright blue flowers, which last a long time in perfection. The young plants are specially beautiful, old plants, unfortunately, becoming unsightly through the loss of the lower leaves, a condition unavoidable in a sub-shrub.

The winter-blooming *Begonias* are universal favorites. *B. Bismarckii*, a garden hybrid of doubtful origin, but evidently related to *B. rubra*, is one of the very best. It is always in bloom, winter and summer, and bears a large truss of lovely pink flowers. *B. semperflorens rosea-gigantea* is another useful variety for any purpose. It produces handsome cymes of red-rose flowers, excellent for bouquets. *B. incarnata*, *B. Socratana*, *B. Verschaffeltii* and *B. Scharffiana* are among other useful kinds.

French Cannas have lately become popular for winter decoration. After a short season of rest they will start up again

and bloom and increase in size all through the winter. These notes presuppose the careful and appropriate use of Palms, Ferns and other good-foliaged plants.

Wellesley, Mass.

Orchid Notes.

A LARGE plant of *Epidendrum cochleatum* in bloom is an interesting, and, in its own way, a beautiful, object. The oblong, compressed pseudo-bulbs are from four to five inches high, and they bear two oblong-lanceolate leaves of rich green color, and somewhat leathery texture at the apex. The leaves are from nine to twelve inches in length, and the erect terminal racemes a trifle shorter. Six or seven flowers are closely arranged at the top of each peduncle, and the drooping sepals and petals are linear-lanceolate and of a whitish or very pale green shade. The lip, however, is the most characteristic portion of the plant, being erect, an inch in diameter, shaped like a cockle-shell, and of a rich black-purple color, with a small area of green at base and apex. *E. cochleatum* is not at all common in cultivation, but it well deserves the attention of gardeners. It should be grown in an intermediate temperature, with the roots in rough peat, sphagnum. Plenty of water and drainage is needed during the growing season. The water should be almost totally withheld for at least two months after flowering, and then the plant may be repotted, if necessary, and again prompted to grow by the application of water. This plant is common in Central America and the West Indies, and it is also said to occur sparingly on the coast of Florida.

Epidendrum nocturnum, the night-scented *Epidendrum*, is a widely different plant, also in flower now. This species was one of the first epiphytal Orchids cultivated in Europe, having been introduced from Martinique in 1816. The much-compressed stems are from twelve to eighteen inches high, bearing several oblong leaves, from three to four inches in length, on the upper portion. It is rare that more than one flower appears at the apex of a single stem at the same time, but they are produced in rapid succession for months together. The sepals and petals are of a greenish or light bronzy yellow color, about two inches in length, sometimes longer, linear-lanceolate, with the edges recurved, so as to give them a cylindrical appearance. The lip is pure white, with a bright yellow surface at the base; three-lobed, the lateral lobes large and spreading, the central one narrow, long and pointed. The individual flowers are borne on long slender pedicels, and they last from three to four weeks on the plant. Their fragrance is strong and agreeable at night, but scarcely perceptible during the day. The plant should be grown in a basket or on a block, with a little rough peat-fibre about the roots. An intermediate house suits it best, and it likes plenty of light. Water should be given freely during the growing period, and a very small quantity will suffice when the plant is flowering or at rest.

Cambridge, Mass.

M. Barker.

Notes from the Harvard Botanic Garden.

ALPINIA NUTANS.—In the general appearance of its stems and foliage this plant resembles a tall-growing *Canna*. It is from ten to twelve feet high, quite rigid and erect. The oblong lanceolate leaves of deep green, with paler midrib, are about two feet in length and six inches wide, the long sheathing petioles circling the stem from the base of the blade. The tubular flowers, each of which measures two inches in length by one and a half inches in perpendicular diameter at the mouth, and one inch horizontally, are borne in large pendulous racemes eighteen inches long. There are in each raceme from thirty to forty such flowers, the outer parts of which are pure white, tipped with bright rose. The central portion or lip is quite large in comparison, and very beautiful. The sides at the base are incurved, covering the conspicuous column-like arrangement of reproductive organs, and the margin fringed in front. The ground-color is a rich orange-yellow, with a profusion of deep crimson markings in the centre. The flower-buds are extremely pretty even before they expand. They are of ovate, oblong form, the color being pure waxy white, tipped rose. *A. nutans* is an excellent plant for large conservatories and Palm-houses. The foliage is pleasing at all times, and the flowers appear at various seasons, the racemes retaining their attractiveness about two months. Small specimens of the plant have little or no decorative value, but it develops rapidly. Its growth should be hastened until it is of sufficient size to fill a large tub with roots, and then it may be expected to flower freely. Large specimens require repotting about once in three years, and for these a small quantity of lumpy charcoal should

be added to the compost. A large amount of water is required when the plant is growing freely. It is a native of China and the East Indies, having been introduced in 1792, and is easily propagated by dividing the roots.

COMBRETUM PURPUREUM.—Some of the Combretums are pretty generally cultivated in European gardens, and they are very ornamental plants for the warm end of any conservatory. Those in search of plants choice and rare will find much to please them in the best of the Combretums, and they cannot do better than give them a trial. *C. purpureum*, however, is rarely seen even in the horticultural establishments across the ocean, though it is a plant of decided merit. It is a native of Madagascar, said to be commonly cultivated as an ornamental vine in the Mauritius, and, although introduced from the British colony in 1818, it has never become popular. It is of shrubby character, the free-rambling branches being densely clad with opposite, elliptical or slightly obovate leaves of deep green color, and from five to six inches in length, the petioles short. The flowers are loosely arranged in terminal, tapering panicles from twelve to eighteen inches long, and as many across at the widest part. The spreading, five-parted bright crimson corolla is about half an inch in diameter, and the filaments, of similar color, are erect, three-fourths of an inch long, and disposed in brush-like clusters. Our plant bloomed quite freely during the summer months, and is now again on the eve of making another display of flowers but little inferior to the first. It is grown in a pot, the branches trained to wires stretched along the sunniest side of the Palm-house, where they are always fully exposed to light and sunshine. They require a free supply of water in summer, when a thorough drenching with liquid-manure about once a week will also be found beneficial; but the roots should be kept rather on the dry side at other seasons. Cuttings of firm young wood, inserted in sand and placed in a close propagating structure, root freely in summer, and established plants should be so pruned and trained in winter that all the following season's growth may have equal access of light.

Correspondence.

A Spurious *Elæagnus longipes*.

To the Editor of GARDEN AND FOREST :

Sir,—What was said in your issue of November 9th about *Elæagnus umbellata* clears up a mystery of my own garden. That fascinating description of *E. longipes* which appeared in GARDEN AND FOREST December 12, 1888, made me long to possess myself of a specimen. When I received my shrub from the dealer it seemed to answer the description fairly well, though not precisely. This year it fruited, but instead of the oblong juicy berries, "half an inch or more long," I got a crop of puckery little fruit no larger than choke-cherries, and much like them in shape. Neither did they ripen in July, but in late October.

In the light of your recent explanation all is plain. It is clear that the nurserymen have been sending out *E. umbellata* for *E. longipes*. As there are quite likely to be other disappointed ones besides Mrs. Dandridge and myself, I think it might be well if the editor would kindly point out in detail the differences between these two Japanese shrubs. Is *E. umbellata* really worth the ground it occupies?

Marblehead, Mass.

N. A. Lindsey.

[*Elæagnus longipes* was first described by Dr. Asa Gray in 1859 from the botanical collections brought home from Japan by the famous Wilkes Expedition. In cultivation at the Arnold Arboretum it is a perfectly hardy bushy shrub, and at six or eight feet in height it appears to be fully developed, although in Japan, where it is often cultivated for its fruit, it assumes the habit and attains the size of a small tree eighteen to twenty feet in height. The stems and branches are dark gray or dark reddish brown and minutely scaly or dotted, the ripe annual growths being lighter-colored. The leaves are green above, silvery beneath, and noticeably sprinkled with dark-colored dots, more numerous on some leaves than others. They are without teeth, and are variable in shape on different plants; sometimes quite long, and not more than a third as wide, most usually oval or oblong, blunt-pointed and two inches or less in length, or occasionally so broad as to appear almost circular. The flowers are generally pretty fully expanded by the middle of May, and are borne singly or several together in the axil of each lower leaf of

the new growth of the season. They are yellowish within, but silvery and roughly scurfy on the outside, and often dark-dotted like the under side of the leaves. At blossoming time the flower-stalks are hardly half an inch in length, but as the fruit develops the stalks lengthen, until at maturity, in early July, they may average about an inch in length, being a good deal thicker nearest the fruit than at the insertion on the branch. The bright red or orange-colored fruit is oval in shape, blunt or slightly flattened at the ends, the skin thin and covered thickly with minute silvery white dots. The juicy and luscious-looking fruit, though edible and palatable to some people, leaves a disagreeable taste in the mouth, a quality which has been found even more pronounced in fruit that has been cooked.

Under the name of *Elæagnus longipes* some American nurserymen have sold large numbers of an entirely different plant, a species of wide distribution in Japan and China and other parts of Asia, and apparently one of the hardiest and the most northerly in its natural habitat. This is known as *E. umbellata*, under which name it is properly distributed by some of our nurseries. This may be distinguished from *E. longipes* by its lighter-colored bark, silvery gray, instead of reddish brown, young branchlets, a larger proportion of the branchlets being inclined to become thorns—hence the name, "Silver Thorn," sometimes given. The leaves are of a lighter green color, narrower and more rarely marked by dark dots on the under side than those of *E. longipes*. The flowers are white on the inner, densely silvery scurfy on the outer side. They are fragrant, and are often produced in clusters like little umbels. The flower-stalks or pedicels are quite short, and when the fruit arrives at maturity the stalks do not average more than a quarter of an inch in length. The fruit itself is usually red or amber-colored, small, round or oval in shape, commonly about a quarter of an inch long, sometimes less, but on some plants as much as three-eighths of an inch in length. It is often much more thickly covered with silvery dots than the fruit of *E. longipes*, and when fully ripe it has, on some plants, at least, quite an agreeable flavor, which improves the longer it remains on the branches. Sometimes it has little flavor or juiciness, and all the fruit for a good while after it has changed color is rather disagreeable and puckery. On different plants it appears to be very variable in time of ripening, and it persists for a long time in a fresh condition. The plant is in good bloom at the Arnold Arboretum about the middle of June, and the fruit may begin to show ripening colors by the middle of August, some plants keeping their fruit until late in November.

This shrub is larger, more open and straggling and more thorny than *E. longipes*. *E. parvifolia* is another name under which *E. umbellata* is sometimes found. It appears to have been given to a form with the larger, earlier-ripening fruit, but the plant has been found so very variable in different regions that the name of *E. parvifolia* is now generally regarded as synonymous with *E. umbellata*. This species will bear clipping and form a good hedge. *E. longipes* is sometimes to be recognized under the names of *E. crispa*, *E. edulis* and *E. rotundifolia*, given at various times by gardeners. The points of chief difference to be noted in distinguishing these two species of *Elæagnus* are the generally dark aspect of the first, as a whole, the other being much lighter and more silvery; the dark twigs and buds of the first and the usually silvery twigs and buds of the latter; the marked difference in the time of flowering and ripening of fruit; the difference in size of the fruit and the remarkable difference in the length of the fruit-stalks.—Ed.]

Flowers at Wellesley.

To the Editor of GARDEN AND FOREST :

Sir,—There are just now many interesting things in the greenhouses of H. H. Hunnewell, Esq., besides forced bulbous plants, such as Roman Hyacinths and Narcissi, which are already in full bloom and fragrance. The *Cyclamens* are full

of large flowers in varied colors, and there are many specimens of the Lobster Cactus (*Epiphyllum truncatum*) completely draped in soft rose-purple. The free-flowering *Bouvardias* are grown in generous quantity, and there are few greenhouse plants of such easy culture so generally useful in winter. They are very graceful and effective when in full bloom, and the flowers last well when cut. Specimens of good size may be obtained in a few months by inserting the cuttings in sandy soil and placing them in a hot-bed in early spring. The plants should be grown on in pots, plunged out-of-doors in summer, and removed to their final quarters in September.

The Calla Lily (*Richardia Æthiopica*) spathes are numerous on vigorous plants, and the gardener, Mr. Harris, called my attention to a variety named *Grandiflora*, in which the fragrance of the flowers is particularly sweet and strong. The Little Gem variety is also grown, there being a number of plants in promising condition, though Mr. Harris is of opinion that it will in usefulness prove far inferior to the well-known type. A large standard bush of an *Abutilon*, with light yellow, bell-shaped flowers, is rich in the luxuriance of its foliage and in quantity of bloom.

Solanum capsicastrum is grown on account of its ornamental fruits, which are as large as the white fruits of the Snowberry (*Symphoricarpos racemosus*), globular in form, bright red and glossy. There are also some specimens of *Solanum ciliatum*, a spiny plant with large Oak-like leaves and bright red fruits about the size of walnuts. Both these plants are highly effective and very desirable for a cool greenhouse.

A large plant of *Pleroma macrantha* in a cool conservatory was a grand sight, with its rich purple blossoms, a short time ago, and a few flowers still remain. Were the plant in a somewhat warmer house it would bloom more or less freely all winter. *Anthurium Scherzerianum*'s twisted spathes of vivid crimson are very showy, and produced in fair quantity on a medium-sized plant. There are still a few of the beautiful pinkish bracts on *Bougainvillea glabra*, a summer-flowering climber of rare excellence, and the large scarlet bracts of *Euphorbia pulcherrima* make a bold mass of cheering color. *Bignonia venusta* is grown in a warm house, the old stems covering a large area of the roof, and the young branches, laden with opening flowers, hang down in streamers of orange and green.

The numerous and healthful foliage-plants are being slowly crowded out by the introductions of Orchids. Mr. Hunnewell's collection of the latter plants gives every indication of speedily becoming one of the most important in this country, and they are in most competent hands, judging from the superb growth they have made during the past season. The *Phalænopsis* are now showing some extra strong scapes, and the plants of this group are in a condition rarely equaled. The following, among the plants in flower, are especially noticeable as showing the highest state of cultural development: *Cataseum saccatum*, *Cattleya bicolor*, *C. Gigas*, *C. Harrisii*, *C. maxima*, *Cypripedium callosum*, *C. Dominicanum*, *C. Spicerianum* (several plants of this species bearing two or three flowers to a scape), *Dendrobium Dearei*, *D. formosum*, *D. Phalænopsis*, *Lælia pumila* and its variety *præstans*, *Odontoglossum Harryanum*, *O. grande*, *Vanda Kimballiana* and *Zygotepetalum Mackayi*.

Boston, Mass.

Casual.

The Use of Cultural Directions.

To the Editor of GARDEN AND FOREST:

Sir,—The desire expressed by a correspondent for information which is adapted particularly to American gardens is a very natural one, and is probably the outcome of the idea that foreign practice differs in a great degree from our own, as it often does, just as garden practice in California must often differ from that of Massachusetts. One who undertook to give advice from the American standpoint would be confronted at once with conditions as diverse as can be imagined, since the United States offers about every known variety of climate, exposure and soil. Latitude furnishes few indications, as isothermal lines do not follow geographical abstractions. And temperature is only one factor in cultivation. What is the average moisture? Is it well distributed, or does it occur all in a given season? Then follow questions of fertility and the mechanical constitution of soils at different seasons, and many other problems of equal moment. In fact, any one who attempts to cultivate the smallest portion of the earth's surface soon discovers many things not mentioned in any cultural manual, and he finds that his operations must in many cases be tentative. Cultural notes are often very useful, but at best are mere relations of personal experience, and whether

they are made in England or New Jersey they must be modified as the intelligence of the cultivator decides.

The cultivator of the hardy garden, to consider a definite style of garden, is ever at the mercy of the elements, and the interest in the hardy plants is heightened by the never-ending struggle with nature. The popular idea of a hardy garden is that it is one where everything once planted goes on vigorously from year to year and from strength to strength with little or no attention. This is quite true of some strong-growing things, as *Phloxes*, *Pæonies*, *Funkias*, a few *Sunflowers*, etc., but usually, even with these, when unattended to, there comes a time when nature has her revenges. But these plants are of moderate interest beside the numerous hardy species which will naturally be sought for in a good hardy garden, and be a source of more or less perplexed pleasure to the grower. In late winter and early spring, if one watches the fields, he will discover that nature is apparently engaged with frost and sun-warmth in destroying all traces of vegetation. With a heave here and a heave there the mighty but quiet frost lifts out of the soil every root not safely anchored. It is only the great abundance of plants and seed which prevents the entire extermination of many species. If this is true among native plants, how much greater would be the destruction of exotic plants, which are at a further disadvantage by their small numbers in comparison with the native kinds?

The winter care of a hardy garden may seem the further end of its culture, but it is really one of the things to be considered in first planting. The careful, observing gardener will notice that even a very small garden has considerable diversity, if not of soil, at least, of warmth and natural drainage, and will always have it mapped in his mind with situations which seem suitable for plants of different constitutions. By observing the disappearance of snows from the garden one can gain a very good idea as to where it may be best to place certain classes of plants. Where the snow lies longest is, of course, the place to plant such things as are apt to start too early in the year, or are easily, from their nature, thrown out of the ground by frequent freezings and thawings. Where the snow disappears promptly rapid changes are apt to be the order of the season, and no exposed crowns or perennial leaves are safe, though if sheltered well from the north such a place may make a good early garden for bulbous plants. It is attention to seemingly small details and careful observation which makes the garden a success and a pleasure. How to make plants grow is knowledge not given to man, but if we will plant them carefully, attend to their wants faithfully and intelligently they will often grow for us.

Elizabeth, N. J.

G.

Horticultural Education.

To the Editor of GARDEN AND FOREST:

Sir,—Your editorial expression upon horticultural education is encouraging. I am glad that you appreciate the fact that a farmer's boy or girl may be greatly benefited by even a short one-term course of lectures, reading or practice. Our own institution, in common with others, now offers such a short course, and we have for some time considered the feasibility of instruction by correspondence, a plan which seems to me to be capable of good results. As you say, these courses cannot make finished gardeners, and, for myself, I do not look upon the mere information or instruction which the courses give as their chief value. The important result is inspiration. Kindle the spirit of enthusiasm in a youth; let him know what to look for; show him that all the simple amenities and ambitions of life are possible on the farm. When he once grasps this broader horizon of life, the farm is a new sphere, and citizenship has new hopes and responsibilities. Our people must be citizens as well as good farmers and good mechanics. I imagine that all the agricultural colleges which give short or special courses find that these are feeders for the long or general course. Our senior class is usually as large as the freshman class; sometimes larger. This shows that there is a contagion about education which it is difficult to resist. We all want to extend the college, university, experiment station; in short, the education spirit. Then we want all those who desire to take definite and prolonged instruction. We cannot yet hope to make every farmer a college graduate, but we hope that every one in the land shall feel something of the inspiration which comes from the newer and broader life.

Cornell University.

L. H. Bailey.

Notes.

Mr. W. J. Gordon, who died a fortnight ago in Cleveland, provided in his will that his extensive and beautiful pleasure-

ground, known as Gordon Park, should be given to the city of Cleveland under certain conditions. Mr. Gordon was a great lover of plants and flowers, and during his life his pleasure-grounds were freely open to the public on stated days.

For the purpose of awakening and increasing the interest in aquatic plants, and in Water Lilies particularly, Mr. W. W. Lee, of Northampton, Massachusetts, offers to send to any subscriber of GARDEN AND FOREST, photographs of *Nymphaea dentata*, *N. gigantea* and *Victoria Regia* Randi, all natural size, at cost and expense of sending, and also a large photograph of a pond containing a *Victoria Regia* and many tender aquatic plants in flower.

A writer in the *Gardeners' Magazine* describes an old tree of the Gloire de Dijon Rose in the garden at Blake House, near Taunton, England, which was budded on a brier-stock thirty-two years ago. The stem at eighteen inches from the ground is ten inches in circumference, and it is of standard form, five feet six inches high. The branches have a circumference of twenty-four feet, and the vigorous plant still blooms abundantly until late in the autumn, and shows no evidence of exhaustion.

At the Chrysanthemum Show in San Francisco last month, one of the features was a "petal-guessing contest," for which a premium of \$50.00 was offered by the Sherwood Hall Nursery Company. A large bloom of the variety known as "Prince" was set up on a black mounting so that its outlines could be distinctly seen, and visitors crowded around to try for the prize. More than 6,000 votes were cast, and the bloom was estimated to contain all the way from 120 to 10,000 florets. The actual number was 512.

Rev. Edward Everett Hale thinks that much of the eager talk in English prose and poetry about the beauty of hedge-row flowers is due to the fact that the rows are so high that one who walks or even rides between them in a carriage can see nothing else. In a guide-book made for pedestrians, travelers are especially directed in one place to look out for a gate, through which they can catch a glorious view of the sea, which, for two miles or more on either side, is screened from view by the high hedge.

M. H. Correvon, Director of the "Jardin Alpin d'Acclimatation, Geneva, writes to the *Gardeners' Chronicle* that he has received from the mountainous regions of Servia and Montenegro several interesting plants which have not been introduced into cultivation. One of them is *Chrysanthemum cinerariæfolium*, which has large and beautiful flowers and long-stalked leaves, double-lobed. Another is *Alyssum repens*, from Mount Durmitor, where it was collected at an elevation of 6,000 feet. It is a dwarf-spreading species, with yellow flowers, which surpass in beauty those of most other *Alyssums*. From the southern Caucasus, at an altitude of 2,000 feet, comes a beautiful Foxglove, *Digitalis ciliata*, which resembles *D. grandiflora* somewhat, and is an erect, graceful plant, which flowers freely from June to September.

It is said that the portions of Russia which are now stricken with famine are in the region of the black soil, which has always been considered one of the most productive portions of Europe. If this is true, the evil is, without doubt, largely the result of the same wasteful cultivation which has been going on in some of our own prairie soils. But, perhaps, the deforesting of the country is responsible for some of the difficulty. The destruction of the forests is spoken of with great positiveness as the cause of the famine by many observers, and although it is the fashion to exaggerate the influence of forests on climate, or, at least, to speak of their influence without knowledge, nevertheless it is quite probable that the forest which once protected the fields from hot winds in summer, and from equally destructive winds in winter, may have done much to mitigate what would otherwise be a rigorous climate.

Dr. Hoskins sends us a photograph of a Willow-tree which stands in Waterbury Centre, Vermont, near the base of Mount Hunger, with a trunk measuring twenty-four and a half feet in circumference and a symmetrical top which shades an eighth of an acre of ground. One who knows the early history of the Willow testifies that in 1840 it was a tree something like six inches in diameter, which had grown from a walking-stick driven into the ground a few years before by some children. In that year it was cut down deep into the ground in the hope of killing it, but it started a new growth, and has reached its present dimensions in fifty years. The rapid growth of the Willow in favorable localities is well known, and Dr. Hoskins writes of another near his home which sprang from a cane carried by a returning soldier in 1866, and thrust into the soil in his doorway. It is now more than four feet in diameter, with an im-

mense top, and bids fair, at an equal age, to reach the dimensions of the one before spoken of.

The unpacking, sorting, repacking and forwarding to all parts of the world of dried figs occupies more than half of the laboring population of Smyrna during five or six months of the year. Consequently the arrival of the first consignment of the fruit from the orchards is a great popular event, called "The Feast of the Figs." This year the harvest was magnificent, and a very joyous manifestation took place at the railway-station when the first train arrived, with its cars wreathed with garlands and its locomotive covered with flags. The barrels were quickly unloaded and placed on camels decorated with ribbons and flowers, and the procession started for the emporium, followed by a great crowd dancing to the sounds of music, and the evening was given up to concerts, balls and rejoicings.

The second part of Mr. Romeyn B. Hough's novel publication, *American Woods*, is quite as valuable as Part I., and we are glad to know that Parts III. and IV., each containing sections of twenty-five species, will be issued before the close of the year. These wood-sections are beautifully mounted, and they display the soft tints and delicate lines of the grain in a very interesting way. The slices are so thin that the light passing through them reveals many points in the structure of the wood which would otherwise escape notice, and as they are cut in three directions, across the grain and with it, and show both the heart-wood and sap-wood, they are very complete and instructive. With the specimens comes a pamphlet of text containing much accurate botanical and general information in reference to the trees. The collection ought to be in every public school and library in the country, and it would be an ornament to any parlor-table. Specimens of the woods are also mounted for use in stereopticons in slides of standard size, which show a circular field two and three-quarters inches in diameter. Mr. Hough's address is Lowville, New York.

Mr. L. Eugene Mouline, of the Department of Ardèche, in France, has invented a plan for drying potatoes. They are first crushed, after which the water is squeezed out. The compressed pulp is then separated into pieces and put into an oven, moderately warmed, where it remains until it is thoroughly dry and has taken on a light yellow tint. The temperature is high enough to impart an agreeable flavor to the product, but not high enough to completely transform the starch into dextrine. This new article of commerce, which can be kept an indefinite length of time, has been called torrefied potato-pulp. It can be used in a raw state for fattening domestic animals, and can be converted into a purée for human food by boiling water. It is also ground and made into a light yellow flour, which is mixed with wheat or rye flour and baked into a bread, which is very digestible on account of the partial conversion of the starch into dextrine. According to *La Nature*, the inventor hopes that this flour will be found advantageous from an economic point of view, and that its introduction will cause an increase in the cultivation of potatoes, which will be sufficient during years of drought to make up for a deficiency in the crops of cereals.

An act was passed at the last session of the Ontario Legislature which forbids the spraying or sprinkling of fruit-trees while they are in bloom with any mixture containing Paris green or other substances poisonous or injurious to bees. This legislation is based on the belief that bees are important factors in the production of fruit by helping on the process of fertilization, and that spraying the fruit-trees while they are in blossom will work injury to the fruit-growers as well as the bee-keepers, since it has been observed that since the introduction of the practice of spraying during the time that orchards are in bloom large quantities of bees have perished, presumably of poison. It is held, too, by some men, that honey produced from blossoms which have been sprayed with insecticides is a dangerous article of food. It is also argued that it is a waste of material and labor as well as of fruit to spray the trees while they are in blossom, since the plum curculio is not likely to be present to any extent until the fruit is set and the codling moth also deposits its eggs in the blossom end of the young apple just after the fruit is set. That portion of the pistil upon which the pollen falls is exceedingly tender and sensitive, and it is held by some authorities that the application of such substances as Paris green injures it to so great an extent that the process of fertilization is affected and the development of the fruit checked. A bulletin just issued by Professor Pantou, of the Ontario Agricultural College, upholds the law as in accordance with the teaching of science, and hopes that efforts will be made to have it thoroughly enforced.

Tree Butchers.

IN one of the cities of New Jersey we saw last week a row of Norway Maples where the professional tree pruner had been at work. These trees had been planted more than twenty years, and had made a good even growth, branching some eight feet above the walk from straight trunks which are now about a foot in diameter. All the large limbs had been sawed off a few feet from the trunk, and from the remnants of these limbs an occasional stub was left projecting, so that practically nothing remained of what once was a tree but a mutilated stump. All the trees were literally ruined, and ruined, too, by those who meant to do a friendly act—ruined, through ignorance, by the very process which was intended to prolong their lives and add to their beauty and usefulness.

The men before whose grounds street-trees are planted usually know nothing about them, and cannot even call them by name, so that when a pair of these professional trimmers, with their equipment of ladders, saws and axes, appear, the proprietor is likely to be impressed with the superior knowledge of these supposed experts, and when they assert that the trees are all growing out of shape, or that their vigor needs to be re-enforced by some pruning, he surrenders at once, and the amputation begins. What will happen next year is that the tree, in its effort to make good its loss of vital organs, will send out from adventitious buds a profuse growth of slender twigs, and these will carry an abundance of leaves, so that the stump will uphold a globular mass of foliage. These leaves will help to prolong the life of the tree by digesting the food taken up by the roots, and although they will appear rank and vigorous, they are premonitions of death rather than promises of new life. Fungi will attack the raw wounds at the extremities of the amputated limbs, and they

will begin to rot. The decay will soon eat its way down to the base of the branches, and these will fall. The trunk itself will then be attacked, and the disfigured tree is doomed to certain and early death.

Now, street-trees sometimes need pruning. If, however, they have been originally well selected, a small knife will be all that is necessary, for a few years, to remove an occasional branch that starts out in the wrong place. There is rarely any necessity of cutting off a large limb. If this necessity ever does come, the limb should be cut off close to the trunk and the place smoothed over and painted, so that the wound will be ultimately covered with healthy bark. We have often explained that wherever a stub is left this must inevitably die, and as the trunk grows about it there will be a plug of rotted wood where the branch originally grew, and the disease will eat inward and downward as the water soaks in from without. After street-trees have attained mature size, pruning is rarely needed beyond the occasional cutting away of a dead branch or the removal of one which interferes with another.

In most cities property-owners are not permitted to cut down a tree along the street front of their own grounds without the permission of the city authorities. In many of these same cities, however, every owner has a right to prune his trees, and when such an owner listens to the persuasions of the professional trimmer, his trees, which have been fortunate enough to survive the attacks of the various corporations which operate wires and chop off branches which seem to be in their way, are menaced with a still greater danger. The truth is that the street-trees of every city and town should be in charge of some officer who is acquainted with their requirements. The superintendence should begin before the trees are planted. The officer should see that no species are planted which are not suitable for street-trees, and that only well-grown and healthy individuals of these species are selected. They should then be planted at proper distances and with all due care. They should have constant supervision and protection not only against the attacks of insects and disease and injuries inflicted through wantonness or carelessness, but against the wounds of ignorant pruners. Better have no street-trees whatever than trees which have been abused until they are objects of pity.

It lacks some months yet of being two years since the act was passed which conferred upon the President the authority to proclaim reservations of forest-lands. Six reservations have already been made, and, altogether, 4,500,000 acres of timber-land have thus been set apart, while twenty-six other locations are under examination by the General Land Office for the same purpose. This withdrawing of forest-land from sale is the first essential step toward any successful policy for preserving the public timber-lands, but, as we are just reminded by a circular of the American Forestry Association, the true policy is not one of total exclusion from forest-land, but rather of opening such land for rational use; that is, forest-lands must not only be protected from fire and plunder, but provision must be made for cutting the timber under proper supervision and precaution, so that the forests will serve their highest purpose in the present without any injury to their future. The eleventh annual meeting of the American Forestry Association will be held at Washington on the 20th of the present month, and the aim will be to prepare for some efficient administration of the public timber-lands which have been or are to be reserved. The bill of Senator Pad-dock, which is now on the calendar of the Senate, contains many good provisions, and is an improvement on all former bills which have looked toward a comprehensive administration of our forest-domain. The present meeting will be largely devoted to a consideration of this bill, with efforts to secure the passage of such of its provisions as seem to be of immediate necessity. Nothing but good can come from a full and public discussion of the merits of the measure now before the Senate, and it is to be hoped

that the meeting will be fully attended by representative men who are interested in the establishment of a wise national forest-policy.

In no part of the world are so many Mushrooms raised for the market as in the vicinity of Paris, where they are cultivated in the long subterranean quarries which produce the stone of which the better houses in Paris are built, and probably nowhere else is so much skill and intelligence shown in the management of the Mushroom-beds. Occasionally the plants are attacked with parasitic diseases, and the Mushroom-growers are quick in recognizing the first appearance of several different maladies. Professor Costantin, of the Ecole Normale Supérieure, has recently made a scientific study of Mushroom-diseases, and has been able to detect the causes of several of them.

The two principal diseases are popularly known as the molle and the goutte. In the molle, or mole as the name is now more frequently spelled, the growing Mushrooms are much distorted, at times so much so that the gills and top of the mushroom can no longer be recognized, and it looks more like a small round puff-ball. The molle is due to the growth of parasitic fungi known to botanists as *Mycogone* and *Verticillium*, forms which are stages of development of species belonging to the genus *Hypomyces*. The goutte, a disease which, apparently, does less harm than the molle, is recognized by the appearance of drops from the size of a pin-head to that of a pea, followed by discolorations on the surface of the mushroom. Professor Costantin believes that the goutte is caused by the growth of bacteria.

Professor Costantin has also studied the diseased conditions of the spawn, what is called by the French *le blanc*, used in starting the Mushroom-beds. What is called the *vert-de-gris*, from its color, is due to the growth of a new species of fungus, *Myceliophthora lutea*. The *plâtre*, which makes the beds look as if they had been powdered with plaster, is due also to a new species, *Verticilliosis infestans*. Besides the *chanci*, recognized by the rancid odor, which causes trouble in winter, there is a small gnat which is very destructive to the Mushroom-crop in some of the quarries.

New England Parks.

THE PROJECTED PARK SYSTEM OF PROVIDENCE, RHODE ISLAND.

THE beautiful city of Providence has awakened to a sense of the importance of preserving some of the picturesque forest-land lying at her gates, before it is too late to acquire it at reasonable rates. Certain public-spirited gentlemen, recognizing the great advantages of the situation, have combined to urge upon the city government the purchase of some fine points along the Blackstone River and the bay, and have in energetic publications set forth the wisdom of adding to the land already acquired, other well-wooded and historical regions, so that in time a connected system of parks and parkways may wholly encircle the town, and render it a more attractive dwelling-place than ever.

For such a system the city is exceptionally endowed by its surroundings of hills and water. At its southern end it touches upon Narragansett Bay; the broad Seekonk flows along its eastern border; on the north-west and north are chains of lakes connected by streams; on the south and south-west large ponds lie close to Roger Williams Park. There are, besides, numerous little rivers which flow from the neighboring hills in the upper part of the town, and the broad estuary, known as the Providence River, which makes up into the heart of the city, where it is crossed by bridges. The residences of the richer portion of the population are situated upon the brow and slopes of a steep hill, from which an extensive prospect is commanded, while the business portions lie below, along and across the river, with a broad plain, in which to expand, stretching away to the south and west. Here in the business centre is a tidal basin, known as the Cove, which is being filled up at great expense, some authorities think to the detriment of the river, which needs just this basin to catch the deposit of the tides, and prevent the shallowing of the channel. A great and wise effort was made to turn this reclaimed land

into a pleasure-ground by retaining a part of the tide-flow by means of gates, and surrounding these lakes with trees and greensward, in which case it would have afforded an attractive breathing-place in the very heart of the city. But the property has largely passed into the hands of the railroad company, and will probably ultimately be devoted to screaming and smoky engines and to rattling cars. Fortunately, the opportunities of the outskirts are sufficient to still afford spacious grounds in all directions, to which communication by land and water will be easy, if the projected park system is carried out, as it bids fair to be.

At present the only large cultivated park that Providence possesses is the tract which will soon amount to about 400 acres, known as Roger Williams Park; 104 acres of this land were bequeathed to the city in 1871 by the will of Betsey Williams; it is diversified with hills and dales, trees, lawn and water. There are fine woods of Oak and Pine, a large artificial lake of thirteen acres, adapted for boating in summer and thronged with skaters in winter, and near at hand is a large sheet of water known as Cunliff Pond, which will form a most beautiful addition to the grounds when the necessary arrangements for incorporating it into the present area are completed. The house, 123 years old, formerly inhabited by the testator, is still preserved in the grounds—a quaint old-time cottage furnished in antique fashion, and now used as a retiring-room for mothers with children.

Near the entrance is the statue of Roger Williams, by the Rhode Island sculptor, Simmons, representing that worthy high in air, with the muse of history writing his name upon a tablet at the base of the pedestal. Other sculptures ornament the park, among them a bust of King Ferdinand of Naples, the last Bourbon king, which was brought home from Naples, after Bomba's flight, by an enterprising citizen, who purchased it when it was rescued from the enraged populace, and buried to prevent its destruction. After serving as a rather incongruous ornament of the front yard of the proprietor for some years, it was transferred to these leafy shades, where it must afford much satisfaction to the Neapolitan organ-grinders when they take their recreation in the park. There is near the entrance a building where wild animals are accommodated, and hard by the playful buffalo disports himself with deer in a private yard of his own, his attentions having proved too much for his former companion, a goat, whom he once lifted over the fence in his high spirits, and put an end to him forever. The deer, being more nimble, are able to elude him when he attempts the same pleasantries with them, and the noble antlers of one of the stags looked as if two might play at the game of hooking, should the buffalo be again inclined that way.

A prettier sight than this park in the winter-time when snow is on the ground it would be hard to find. A broad road, some three miles in extent leads to it, which is thronged with the fine equipages for which Providence is famous. The sleighs jingling with bells drive with speed over the course, and then circle about the pond, while their occupants amuse themselves from amid their furs by a sight of the gay figures of the skaters, who come and go among the trees which branch over them, and follow in their flight the graceful windings of the icy course over which they skim. It is like a miniature Bois de Boulogne, with all this luxury and joyous sport, this kaleidoscope of moving figures, the trees bordering the drive-way, the foot-passengers gathering in groups to watch the flying skaters, and here one best recognizes the wealth for which this growing city is famous, and the general well-to-do condition of its inhabitants.

In addition to this park, which is greatly prized by the citizens and which the proposed additions will render a really important pleasure-ground, the city has recently acquired the Thomas Davis estate, a tract of thirty-five acres, lying within its limits, about a mile from the city hall. This charming spot, happily diversified with woods, meadow, upland, hill-side and ravine, and easily accessible by horse-cars, is a most desirable possession for any town. A forest of a century's growth ornaments the steep hill-side and ravine, through which a running brook finds its way, and from the plateau, which stretches away to the south, in front of the stone house formerly occupied by Mr. Davis, there is a beautiful view of the valley of the Woonasquatucket, the surrounding hills, and the city itself, with its clustered houses and its manufactories. The steep sides of the ravine, at the bottom of which the brook flows, are heavily wooded, and the rounded knolls approaching the ravine add to its picturesque beauty. The woods, which cover some acres of the grounds, abound in Oaks, Hickories, Birches, Chestnuts, with a mingling of Ashes, Elms, Maples, Hornbeams and other varieties, while Pines and Hem-

locks and Cedars add to the charm of the spot in winter-time. The largest Canoe Birch in the state stands at the foot of the bank, not far from the stone bridge, and there is a fine variety of shrubbery scattered about the place in pleasing groups.

Upon the borders of the Seekonk River, in the hilly eastern portion of Providence, a beautiful little promontory, containing about five acres, has been presented to the city by two citizens, Mr. W. P. Vaughan and Mr. Moses B. Jenkins. This wooded bluff, still wild and uncultivated and abounding in Oaks, fronts upon the Seekonk River, and commands a delightful view of that broad stream and its banks. It is called Blackstone Park, and a drive along the shore is in contemplation, which, when developed and extended past the spacious grounds of the Butler Hospital, which kindly consents to the use of its long river-front for this purpose, will furnish a most attractive promenade for carriages, bicycles and pedestrians. This parkway, called the Eastern Boulevard, will be a mile and three-quarters in length, and is to be two hundred feet wide, the central portion to be ornamented, and on each side a driveway forty feet wide. Through the ornamented portion a cable-road will be run, and provision made for foot-passengers. This drive, it is hoped, will be extended by Pawtucket, to whose borders it leads, for a corresponding distance through its own territory. In summer little steam pleasure-boats can easily run along the river to Field's Point, now belonging to the city, which is at present an uncultivated sandy cape running out at the point where the Seekonk, otherwise known as the Blackstone, empties into Narragansett Bay. This point, when properly planted and laid out as a pleasure-ground, will form a healthful and cool resort for the crowding inhabitants of the south-eastern portion of the city, and is separated from the Roger Williams Park additions by only a short drive, that could readily be made available as a parkway. It commands a fine view up the river and down the broad bay.

Numerous squares of one or two acres are scattered about the city as welcome breathing-places for the tired inhabitants, but the public-spirited gentlemen who have done such good work in the past have still more comprehensive schemes for the future. The Public Parks Association, with the enthusiastic and energetic head of the Friends' School, Mr. Augustine Jones, as its President, are urging the purchase of a great open space on the north of the city, formerly occupied as an encampment by the French in the time of the Revolution. Here are the cellars of the dwellings they once occupied, and, as Rochambeau Park, this fine tract with its wild landscape, is capable of becoming by cultivation a worthy monument to our old allies. On the north-west side of the city is a stretch of young timber of some seventy acres, known as the Bradley Woods. Among the young and thrifty trees are some venerable specimens of the former forest, and here it is hoped that the city will acquire another park which will be found already provided with a carefully tended forest of some fifty years' growth. From this point a fine view is to be obtained with a far-away hilly background.

Not satisfied with this even, the Park Association is agitating for the acquirement of a hill called Neutaconkanut, which is the end of a high promontory of land, projecting to the south from a range of hills into the large plain which surrounds Providence on the west and south. This hill is about 300 feet above tide-water, and at its base flows the foaming Pocasset River at a higher elevation, making the mean height above the upper plain about 200 feet. This hill was mentioned in the original deed from the Indians to Roger Williams as "Ye greate hill of Notquonchanet on the north-west," and was one of the bounds of the purchase, so that it is of classic interest to the Rhode Islanders. It is already a popular resort for thousands, who make excursions thither for the sake of the noble view which it commands, and to enjoy its fine natural advantages of trees and rocks and rills. There are three summits to the hill, and from the highest of these the eye stretches away south-westward over the closely clustered villages of the little state. Thornton and Cranston, Natick and Pontiac and West Greenwich, with their neighboring hills, are visible, and far-away Coweset Bay, and the white sails in the West Passage, with the islands scattered here and there. On a clear day Newport itself is visible, and the whole extent of the island of Rhode Island. To the east are more villages, and Providence River in its whole brief extent, from Rocky Point to the city, with the mill-covered hills of Fall River in full view. Then more hills, and Providence itself, with its extended suburbs, its busy factories, its lofty spires; while northward the view is bounded by other ranges of hills, until we are conscious that we are looking upon one-fourth of the area of the thriving little state, and have in view the homes of seven-eighths of its swarming and prosperous inhabitants. From the other sum-

mits one can see an equally striking spectacle of beauty and prosperity, one of the most pleasing being that of the fertile Pocasset valley, with its hundreds of acres of cultivated land, its farms and farm-houses and tiny villages. Through this valley winds a road which divides it, and bounding it on the west rises a darkly wooded range of hills stretching from north to south.

"Probably no spot in Rhode Island," writes the President of the Park Association, "equals this in those attractions which are the essential requisites of a rural park. Few have a more attractive outlook. Its beauties are natural, just as God made them. Huge rocks crop out boldly in various localities. Rocks, summits, hillocks, valleys and ravines seem to have taken their places without order, yet are they the more picturesque and varied. No building encumbers it, . . . thrifty woods have sprung up over an extensive area of the hill. Pure water flows from never-failing springs. The views from its summits of cities, country, wooded valleys and shining sea are far-reaching and grand. Add to this the great rocks and lovely ravines running down the slopes of this hill, and the whole combines in furnishing the natural beauties and essentials of a unique and noble park."

If the city of Providence avails itself of its advantages it will soon be unrivaled as a possessor of desirable recreation-ground. Its own singular beauty of situation demands the retention of such open spaces as may command the lovely prospect that opens about it in all directions. Prosperous, comfortable, growing with rapidity in extent and population, the chief city of Rhode Island does well not to fall behind in the march of taste and improvement which has begun in our land.

The Weeping Spruce.

IT had been my desire for the last three years to visit the group of Weeping Spruce (*Picea Breweriana*) growing on the summit of the Siskiyou Mountains, in Siskiyou County, California, and having learned this year that the other conifers in the northern part of the state were seeding I determined to visit the grove and obtain seed, if possible. In company with my father, Mr. Robert Douglas, of Waukegan, Illinois, we went to Grant's Pass, Oregon, the nearest railroad station to the grove, where we procured horses and drove the first day to Andersons, about twenty miles from Grant's Pass. Owing to heavy rains we did not reach Waldo until about four o'clock next day, where we engaged a guide, saddle-horses and pack-animals, and left for the trees early the morning after, reaching the "Big Meadows," on the summit of the Siskiyou, about four o'clock, having traveled about twenty-one miles in a horizontal direction and more than one mile in altitude. Waldo is about 1,500 feet above sea-level, and our camping-place was about 7,500 feet. The trail over which we came was made by a Spanish packer for the transportation of provisions from Waldo, Oregon, to Happy Camp, a mining town in California. It is a fair trail for such a rough country, but it is not a macadamized road. We slept that night with some evergreen boughs under us and the blue sky over us part of the night, and the most dense fog I have ever seen for the remainder of the night.

The next morning we walked up the trail about a mile and a half to the few scattering Weeping Spruces, about sixty in number, which had attained a height of twenty-five feet, at which size they begin to bear seed; but we found that most of the trees under fifty feet had very imperfect seeds. The cones are from two and a half to three and a half inches in length and three-quarters of an inch in diameter, of a fine purplish color. They mostly grow on the extreme top and ends of upper branches. The beauty of the trees far surpassed my expectations. They have the true Spruce form, tall and symmetrical, with horizontal branches, and a beautiful green color. In their general features they resemble a well-grown Norway Spruce, but their distinguishing beauty is in their long, pliant, pendulous branchlets, which hang straight down from the branches to a length of six or eight feet on the older trees, while they are no larger round than a lead-pencil (see page 595). They have a stately grace in calm weather, but their characteristic impressiveness is only seen when the long flexible branches are undulating in a light breeze or streaming before a gale.

The bark of this Spruce is thin, smooth and reddish in color; the wood is white and very tough. The tree felled several years ago by Mr. T. S. Brandegee for the Jesup collection shows no sign of decay as yet. The largest tree in this grove—if grove it can be called, where the trees are scattered over a space of fifty acres, mixed with Firs and Incense Cedars—we found to be by actual measurement 121 feet 6 inches high,

with a trunk two feet eleven inches in diameter seven and a half feet from the ground. Below that height the trunk swelled to a much greater size. Other trees were more than ninety feet high, with about the same diameter. My father left for San Francisco on the second day, but as the trees were seeding heavily I remained ten days longer and collected 800 pounds of cones, out of which we will get some twenty pounds of fine clean seed, the first, I believe, ever collected. I found another grove of about twenty trees some two miles from this one, but could see very few seedlings in either place. In both groves the trees were growing on the north side of the highest peaks, where the snow lies fifteen or twenty feet deep, as the mail-carriers' signs show, and I can therefore believe the Weeping Spruce will be hardy in most parts of the east.

Later in the season I made another trip to these groves to get as many seedlings as I could, and hunt up more trees if possible. Hunters and prospectors reported that they grew in various parts of the mountains, but when these men saw the branches I brought down they admitted their mistakes. Mr. Orrin Russell, who has lived in this part of the country for more than twenty years, and who is exceptionally well informed, reported that a few Weeping Spruces grew on the Coast-range in Oregon. I visited him at his mines after I had collected and shipped the few seedlings I could find on the Siskiyou Mountains, and in company with his brother, Mr. Joseph Russell, found the trees at the place indicated—on the summit of the Coast-range, on the divide between Cañon Creek and Fiddler's Gulch. This is the first time, so far as I know, that any record has been made of these trees in Oregon. We also discovered a few more about a mile south-west of the first grove. They are widely scattered, and in a dense forest of Firs and Douglas Spruce, and taller than those on the Siskiyou Mountains, but have a smaller trunk diameter. We spent two days collecting the seedlings. Mr. Orrin Russell informed me that he knew of about a dozen trees at the head of Sucker Creek, in the Siskiyou, which I would have visited had I not been prevented by heavy snow.

North Carolina Notes.

A WEEK ago I visited Fayetteville, the head of navigation on the Cape Fear River. I have been raising a great number of Tea-plants, and had selected the neighborhood of Fayetteville as a favorable location for a subexperiment station for a Tea-plantation. The place lies in the upper Long-leaf Pine belt, where a slightly undulating section of sandy loam, underlaid with granitic clay, makes a warm soil, which seems peculiarly adapted to tree-growth. There is here an old neglected Tea-plantation, from which good tea has been made for many years. The fact that the plants have survived in a dense thicket of Pine, scrub Oak, Briers and Smilax shows their hardiness, and they seem to be getting almost naturalized; at all events, there are multitudes of young seedlings in the woods about the old plantation. At the time of our visit these plants were full of flowers, but the white petals were browned by the recent frost, though many buds still remained to continue the bloom.

On this old place we found a noble avenue, the trees in which were alternately evergreen Magnolias and Prunus Caroliniana. I have always regarded this last more as a large tree-like shrub than a tree proper. But here they stood almost as large as the old-fashioned Cherry-trees we used to plant in avenues in Maryland, some with trunks eighteen inches in diameter. The Magnolias were of like massive proportions. Nearer the old mansion the land broke into swelling undulations as it sloped toward the river, and here, with admirable taste, has been preserved a large area of the original forest-growth of the Long-leaf Pine. Never in all my experience have I seen a finer growth of this majestic tree, and the crop of seed this year is so plentiful that the ground was fairly covered with the dropping seeds. It may be many years before another such crop is made, for the Long-leaf Pine is rather shy in fruiting. Here, too, on the lawn, were great plants of Gardenia florida, with their latest flowers just crisped by the frost, but with glossy foliage untouched, testifying by their massive growth to the generous soil and hospitable climate.

When my business was over I spent a day looking about the old town for objects of horticultural interest. In one doorway, and only one, I saw Olea (Osmanthus) fragrans of fine size, from whose sweet blossoms the frost had not quite driven the perfume. In this same door-yard Magnolia furcata did not look altogether happy. Just across the street an old mansion had burned down the day before, and I wandered in the grounds, crowded with many interesting plants. Close by the still smoking ruins, two plants of Camellia, to match formerly

fine pyramids, now stood scorched and blackened, while the great Indian Azaleas, that stood by the portico, were evidently killed by the fire. Near by a Cryptomeria, nearly fifty feet high, was completely covered by a giant plant of Eleagnus reflexa. Out of danger from the fire stood the largest Cork Oak I have ever seen, though there is a larger one at Avoca, on Albemarle Sound, from which I have had acorns sent me this season. The Fayetteville people are evidently flower-lovers, for almost every door-yard has its little glass-covered pit for wintering over the pet Geraniums and Callas. The Oleanders kept company with the Gardenias outside, in many places sheltered by dense and closely trimmed hedges of Japan Evonymus. As in most other places, far-fetched things seem to be most valued, if I except the ever-present Laurel Cherry and Magnolia. In one place only I saw some plants of the beautiful Ilex vomitoria. One of these was loaded with its brilliant scarlet berries, looking as translucent as glass beads. I am exceedingly sorry it seems necessary to go back to the name "vomitoria" for this beautiful shrub, Cassine was so much more pleasant. The common name here is "Yaupon," probably the old Indian name. The pretty Laurel Cherry, Prunus Caroliniana, is here called Mock Orange. Osmanthus Americana, the American Olive, one of the handsomest shrubs of our coast, I did not find cultivated anywhere.

The front yards were pleasant, and I strolled around the back streets to peep at the vegetable gardens. Alas, what a poor appreciation people have of their climate. Not a vegetable did I see, except some unhappy, worm-eaten Collards on stalks two or three feet high, and a few Turnips. No Lettuce, no Radishes, no Kale, no Spinach; no cold frames for heading Lettuce free from frost-marks. And yet, in this warm, sandy soil and genial sunshine, these hardy vegetables would be just in their element now. But the Fayetteville gardens showed fewer vegetables than the snow-buried gardens of the north. In my own garden in the colder clay soil of Raleigh there is not a day all winter in which we do not have fresh vegetables from the garden, and here, in a warmer soil and seventy-five miles further south, not a green thing could be seen in the kitchen gardens but that gaunt burlesque of a Cabbage, called the Collard. Only a few days before, I had dug my late crop of Irish potatoes, grown since August, and here was a thriving town living on northern potatoes at \$1.50 a bushel, with stalks of the "roasting-ear" corn still standing in the gardens since the June crop was eaten.

W. F. Massey.

New or Little-known Plants.

A Double Morning Glory.

IN our issue of October 5th, page 480, we spoke of having received from Mr. Curtis A. Perry, of Braintree, Massachusetts, specimens of a double-flowered Morning Glory, *Ipomœa purpurea*, or, at least, of a plant apparently identical with *Ipomœa purpurea* in all its characters except the corolla; the calyx, which is also sometimes doubled, being especially well marked by its shape and pubescence. The leaves were almost as large as those of *Aristolochia Siphon*, and the flowers, which were very much doubled, were a blush white and streaked with light purple. Photographs of the plant showed that it was rampant in growth and profuse in bloom, the flowers standing out boldly beyond the leaves. The seed first came from Mexico three years ago, and the seeds from the plants then grown have produced plants in which for three years the flowers have come true to their double character. The plants begin to bloom out-of-doors in September, but one of them, when cut back last autumn, flourished well as a pot-plant in an ordinary furnace-heated house.

After these notes were published, Mr. Sylvester Baxter, of Boston, wrote us that he was with Mr. Perry, visiting the little tropical city of Cuautla, when they first observed among other plants a strange-looking flower on a vine which was romping over the corridor of the second story of the hotel where they were stopping, and, from time to time, gathered seeds as they ripened. The first year both Mr. Perry and Mr. Baxter raised plants, which bloomed abundantly. The plants flower much later than the single variety, even when growing side by side with it under the same conditions, so that it is difficult to obtain mature seed from outdoor plants before autumn frosts cut

them down. This year they were covered with flowers early in September, and they still presented a good appearance when Mr. Baxter wrote in the middle of October. As to the general appearance of the flower,

Mr. Faxon's drawing, reproduced on this page, very well shows its characters.

In Dr. Masters' *Vegetable Teratology* it is noted that dialysis has been observed in *Pharbitis* as well as *Convol-*

Fig. 101.—A Double Morning Glory, *Ipomoea purpurea*.—See page 592.

he writes that the "numerous petals standing somewhat apart form a light little cluster of striking delicacy, which gives the flower a fluttering or bird-like aspect."

vulus, *Pharbitis* being now included in *Ipomoea* and in the section of the genus to which *Ipomoea purpurea* belongs. It is more proper, however, to call this doubling or

multiplication of the parts of the corolla a case of pleiotaxy. Dialysis is merely the separation between parts primarily undivided, as when an ordinary gamopetalous corolla is divided into five distinct petals. Examples of pleiotaxy among Polypetalæ, such as Roses, Pinks and Anemones, are very familiar, and among Gamopetalæ it has been noted in *Datura*, *Campanula*, *Primula*, *Arbutus*, *Nerium* and *Gardenia*. Dr. Masters makes no mention that it has been observed in *Ipomœa*, or any member of the family, so that this plant has exceptional interest botanically as well as on account of its horticultural value.

Cultural Department.

How to Grow Cyclamens.

THE Massachusetts Horticultural Society, in making its awards last year, gave a premium to Dr. G. C. Weld, of Brookline, for the successful cultivation of Cyclamens, and the Committee on Gardens, in their report, publish a paper by Mr. Kenneth Finlayson, Dr. Weld's gardener, in which his method of growing these flowers is explained, and which we now reproduce :

I sow the seeds about the 1st of December in a compost of fibrous loam and well-decayed leaf-mold, in equal parts, adding thereto a liberal dash of sharp, clear sand, with a further quantity of finely crushed charcoal to keep the whole porous and sweet. The top layer of soil in which the seeds are immediately sown is more sandy and more finely sifted than the rest of the earth. Ordinary earthen seed-pans are used for this purpose, the size depending on the quantity of seed to be sown, an eight-inch pan being sufficiently large to contain two packages of seeds such as we buy from seedsmen. Good drainage in the bottom of the pan must not be neglected. When the seeds are sown and watered well with a fine rose, the pans are placed in sphagnum moss in a mild propagating-bed of a temperature of sixty degrees. I cover the pans with a pane of glass to check evaporation, and thereby avoid the necessity of frequent watering, which ought to be particularly guarded against.

In this temperature, named above, the seeds will germinate in from four to six weeks. After they have formed a leaf they are taken into less warm quarters, and near the glass, but shaded from the bright sunlight for some time. When they have made two or three leaves I transplant them into boxes, using compost much the same as at first, but less sandy, keeping them all the while close to the glass at this period of their existence, in order to have a sturdy and stocky foundation to build on.

They are put out into cold frames early in summer, but still kept in boxes, guarded against cold draughts and sudden changes in the weather, until they get sufficiently hardened to stand some little rough usage. I syringe them morning and evening in hot dry weather, and shade them only from the fierce noonday sun, using lath shades for the purpose; the sash is removed entirely at night when the weather is favorable.

About the 1st of June I pot them into three-inch pots, using at this potting a little well-decayed cow-manure, though sheep-manure is preferable in this compost. They are returned to the frames again, and the pots are plunged up to their rims in coal-ashes. They must be carefully watered for weeks after this operation, and syringing overhead morning and evening must be steadily adhered to. With this treatment diligently persevered in they will be ready for another shift into larger pots about the 1st of September or sooner. At this shift a five-inch pot is chiefly used, this being the pot in which they flower. In a few exceptional cases there may be some plants that outgrow the others to such an extent that a six-inch pot may not be any too large.

The earth used in the final potting consists of three-fifths fibrous loam; the other two-fifths consist of leaf-mold, cow-manure or sheep-manure, and sand, the leaf-mold predominating. Particular care should be exercised when potting the Cyclamen that one-half at least of the bulb be left above the potting-soil, for it is from the top surface of the bulb that the flowers proceed, and if this is placed under the earth the flower-buds will surely rot.

I keep them in their quarters in the frames until the middle of October, before taking them into the greenhouse. After they are brought into the greenhouse they have as light and airy a position as possible. I keep them on the front bench of my Pink-house, in which place they do admirably well, the

temperature at which this house is kept, namely, from fifty to fifty-five degrees, being, in my opinion, the ideal Cyclamen temperature. Indeed, fifty degrees is quite high enough; if kept steadily at that point the plants will be more healthy, and give more and finer-colored flowers.

They begin flowering sparingly eleven months from the date of sowing, but will not come into full flower until thirteen months from that time. I commence stimulating when they begin to form their flower-buds, or sooner should the pots be well crowded with roots, my never-failing stimulant being Peruvian guano, or its best imitation; also, soot and guano in equal parts, mixing them thoroughly before using. A small handful of any of the above fertilizers, dissolved in a six-gallon can full of water, is used once a week should the weather be clear, so that they demand much watering; otherwise, the watering is less frequent.

Cyclamens thus treated will continue to flower until late spring or early summer, when they will show signs of a want of rest; this rest must be brought about gradually, and should never be too severe—that is, never so severe that they will lose all their roots and foliage. Old plants are turned out of the pots some time in June, all the soil is shaken from their roots, and they are then planted in frames, giving them a thorough watering, to settle the soil about them. Afterward a nice layer of short grass is laid over all to keep the soil cool and moist.

I also shade the glass with a heavy coat of paint, and keep the sashes at all times raised at both ends four or five inches, to secure a current of air over them continually. All this done, there is no further attention necessary except a watering at long intervals, until they show some signs of activity, which will be about the beginning of August, when the grass covering should be removed, in order that the young leaves which will now start will have a chance to develop. The soil from this date is kept more moist.

In the third week of August they are repotted and treated like the younger plants—that is, they are plunged in ashes and syringed overhead twice a day if the weather demands. Under such treatment I get flowers as good in every particular from old plants as I do from younger ones, and a great many more of them.

Diseases of the Carnation.

THE enemies of the Carnation are numerous. There is, for example, the rust (*Uromyces caryophyllinus*, Schr.) that has already ruined many beds and many more are doomed. This fungus works in a very obscure manner until it has undermined the constitution of the plant and then it shows itself in great brown dusty patches upon leaf and stem. It is a genuine rust and is closely related to the forms upon grass and grain. Its habits are such that to stamp it out requires the heroic treatment of fire. Spraying may prevent its spread to healthy plants, but nothing can be put on an attacked plant that will rout the deeply seated enemy. A recent letter from Nebraska reported it in that state.

But while this rust is a bad enemy it is not the only one. It gets the credit due to other foes. When samples are sent to the station the first question is this: "Is this the rust?" And more often it is not the rust. One of the most common Carnation troubles is what may be called the leaf-spot. This is caused by a fungus that is somewhat local in its work, at least may be confined to one small spot while all other parts of the plant are entirely healthy. As a rule, however, a plant that is attacked in one place will be a victim elsewhere. These spots are at first somewhat swollen or thickened patches which soon become brown or even almost brick-red in color, and later, dotted with blackish specks, which are the places where the spores are produced and ooze out when mature and the surface is wet. By means of these multitudes of spores the fungus is able to spread rapidly through a house if affected plants are permitted to remain untreated. From the nature of this trouble it is quite evident that it is amenable to the ordinary treatment for fungus parasites.

Last winter a large grower of Carnations volunteered to treat his plants affected with blight as follows: One-half of a large house was sprayed each week with a solution of a half-ounce of sulphide of potassium to a gallon of water. He was so well satisfied that he soon extended the use to all his houses and felt the remedy was of great value to him.

Another Carnation trouble is an anthracnose, and, while this is bad upon large plants, it is the most destructive to cuttings. This *colletotrichum* appears upon the surface of the stems and bases of the leaves as small black specks which, under the microscope, are made up of spores and dark stiff hairs. It is

fond of moisture and is usually located near the base of the plant, but its threads reach throughout an affected plant. When cuttings of a diseased plant are placed in the sand the new conditions of additional moisture favor the fungus, and soon the stem softens at the base and the black specks appear upon the surface of the decaying tissue. Shortly the cutting has rotted off. It is, therefore, very important to use healthy stock for the cutting-bed. This is sometimes illustrated in the propagating-bed when all cuttings from certain plants fail while others from neighboring stock do not.

The last trouble to be here mentioned differs very much from all those above given. The affected plant shows no rust-patches, no colored spots of the Septoria or black speck of the colletorichum species. The whole plant is sick, fails to grow and bloom, and the leaves have a shriveled or somewhat wrinkled appearance, with peculiar minute ashy or yellowish markings, as if something had scratched the leaf internally. There is no sign of any insect at work and no filamentous fungus. Bacteria swarm in the faded streaks, but they may follow

Mrs. Isaac Price very much resembles the old Golden Dragon, except that its flowers are sulphur-yellow. It makes a very handsome low-growing specimen. For the reason that its hooked and twisted petals interlock, it is useless for shipping, either as specimens or cut flowers. Its cut blooms do not associate with other varieties, or even in groups by themselves, but singly in glass bottles or small vases they are superb.

O. P. Bassett is another variety introduced last season, and generally condemned because of its lateness. A friend of mine speaking of it says the color is precisely that of the famous G. W. Childs, deep velvety crimson, while its blooms are equal to that variety in size, and superior in form, being quite double. Whether or not it will make a good bush specimen I am unable to say.

Syringa has always been too late for the exhibitions here. Once it had many admirers; now it is nearly forgotten on account of its lateness. It is an excellent kind for cutting, making large, elegantly incurved, flesh-pink blooms. Molly Bawn is

Fig. 102.—Branchlets of the Weeping Spruce (*Picea Breweriana*).—See page 591

and not precede the disorder; it may be that the trouble is at the root. Persons in sending specimens that answer to the above-attempted description should include the root.

Rutgers College.

Byron D. Halsted.

Late Chrysanthemums.

WHEN the Chrysanthemum exhibitions are over there seems to be a general feeling that the season has gone by. What few remain must be varieties with special qualities to commend them. So late in the season it is hard to endure any but the best, and little attention has been given to late varieties by raisers.

Ethel is a white-flowered, straight-petaled Japanese sort; good either for specimens or cut blooms, and it comes into bloom about Thanksgiving. If kept cool, many flowers will hold until Christmas. Mrs. H. J. Jones is a yellow sport from Ethel, and identical in every particular except the color of its blooms.

C. B. Whitnall, one of last year's introductions, is a Japanese incurved kind of great merit. It certainly is the best late variety of its color, which is a deep claret, with silver-lake reverse. Its habit is all that can be desired, either for bush specimens or cut blooms.

a pure white sport from it, and among the handsomest of the late white bloomers.

Gold-finder has never bloomed in time to exhibit. The blooms are of an uncommon type. Their chief beauty lies in the infolding of the florets with age. A handsome yellow one of this type, named Gloriana, was exhibited by Mr. J. V. May at the late Madison Square Exhibition. White Cap, a recent importation of Halleck's, is another late variety having the same peculiar character of bloom. This year has added some pink and violet colored ones to the list which will be sure to come into favor.

Mrs. Humphreys I consider the best late white for any purpose. It makes a handsome specimen. The blooms are supported on good stiff stems. The florets are stiff, close and straight, fitting it especially for shipment. It is, moreover, sweet-scented. Marvel created quite a sensation a few years ago when introduced by John Thorpe. The blooms are particolored, the outer florets being white, centre bright pink, making a striking contrast. It grows into a cheerful-looking specimen, and very few visitors pass it by without some complimentary remarks. Marvel is seldom seen now, mainly from the fact, I suppose, of its being late. We only once had it in time for exhibition.

Wellesley, Mass.

T. D. H.

The Chrysanthemum is so universally popular in its regular season of blooming—that is, through October and early November—that it has practically displaced the Rose in those two months, and we now have the Queen of Autumn usurping for a short season the place of prominence which has been held for centuries by the Queen of Flowers. Commercial growers are always alert to supply every new want and cater to every change of public taste, and they have, therefore, endeavored to prolong the season of a flower which has been so generally admired. Efforts to force it into perfection before its natural season have been made throughout the country until the attempts to grow early Chrysanthemums are well-nigh exhausted. The late season still remains, and I, with others, have labored hard for eight or ten years to extend the blooming season in that direction. My efforts have met with considerable success, because some of the very latest varieties now in use are seedlings of mine; and yet I sometimes question whether this effort to prolong the Chrysanthemum season beyond its natural limits is wise or profitable. At least, I have never been able to sell as many plants or flowers of exceptionally early or late varieties as of those which are at their best in the mid-season. People seem to grow weary even of beauty when it is overabundant; nevertheless, I will name a few of the late varieties which, in my estimation, are among the best:

Mont Blanc is a large white incurved flower which shows an eye. Its blooming season is from late November till the middle of December. Another good white flower is Flora Hill, a large reflexed variety, which blooms from the middle to the end of November. Mrs. John Westcott is another reflexed white of the same season. John Lane is a soft pink incurved flower which also blooms in late November. The finest late pink in cultivation, however, is Mrs. Charles Dissell, a very large incurved flower, which is good from late November to Christmas. Gold is a deep yellow reflexed flower, which is good during the first half of December, but the best bright yellow of all late-blooming Chrysanthemums, and one of the very best Chrysanthemums of any color is Miss Eva Hoyt, a large incurved flower, which blooms in late November and into December. The latest of all, and a very good one, too, is Mrs. H. A. Pennock, a large incurved bronze-yellow, which commences to flower about the 1st of December and lasts quite through the month. Indeed, it might be called a New Year's flower.

Philadelphia, Pa.

W. K. Harris.

We have found in Philadelphia that Mont Blanc, although not quite up to the exhibition standard, is a first-rate variety, and its natural tendency to come late makes it exceedingly valuable, and the same is true of its lemon-colored sport, identical with it except in color. Gold, which is also known as Mrs. R. Elliott, we have also found good for late work. Potter Palmer, one of the more recent introductions, is an admirable late white, and so is Pelican. Dr. Covert, one of last year's introductions, promises well for late use. It is very large, incurved quite double, and the yellow of its florets is streaked with red. Flora Hill and Mrs. John Westcott are both inclined to be late, and the first-named is one of the very best of keepers we have. In extending the Chrysanthemum season, that is, to secure early Chrysanthemums as well as late ones, there is a great deal in management, and some flowers can be hurried and others held back by one who knows how to select and how to manage them.

Chestnut Hill, Philadelphia.

Edwin Lonsdale.

Orchid Notes.

ZYGOPETALUM INTERMEDIUM is considered by many Orchid-growers a variety of the well-known *Z. Mackayi*, the only difference being that the lip of one is glabrous and that of the other pubescent. The flowers, averaging six in number, are arranged alternately on the upper portion of the erect stem, and are about three inches in diameter. They appear during the winter months, and last some six weeks in full beauty. They are quite fragrant—a fact seldom noticed by writers, and one of some importance to those who might grow the plant in order to cut the flowers for decorative purposes. They are well adapted to this use, as they all expand about the same time and last in water nearly as long as upon the plant. The sepals and petals are oblong, green, richly marked with brown, and spreading in the form of a semicircle; the protruding white lip is rather more than an inch and a half in diameter, the entire upper surface being beautifully marked with purplish blue. Flowering profusely, and easy to grow, the plant must certainly be classed among the most useful of the Orchid fam-

ily. It should be grown in a well-drained pot or pan, using good fibrous peat for the roots. The peat may be lightly surfaced with sphagnum, to preserve the roots in the moist, not saturated, condition, which is always desirable.

PLATYCLINIS COBBIANA is a pretty little Orchid now flowering freely. It is not showy, but its long arching racemes have few rivals in gracefulness. The slender raceme proceeds from the top of the pseudo-bulb, and is about eighteen inches in length, the terminal half supporting from forty to fifty flowers, each nearly half an inch across. They are of whitish color, with conspicuous bright orange lip. *P. Cobbiana*, like the other three species of the same genus which are in cultivation, is a native of the Philippine Islands, whence it was introduced in 1879. No two of the species known in gardens flower at exactly the same time, and thus one is seldom without flowers on some one of the plants where all are included in a collection. *P. uncatata* closely succeeds *P. Cobbiana*, and is followed in spring by *P. glumacea*, while *P. filiformis* (figured in GARDEN AND FOREST, vol. ii., p. 485, under the name of *Dendrochilum filiforme*) blooms in early summer. The last two are especially elegant plants, and the flowers of *P. glumacea* are delightfully odorous. They all grow luxuriantly in a stove, and should be potted in peat and sphagnum, with good drainage, soon after flowering. The roots should always be moderately moist; but when the plants are growing vigorously, the supply of water should be liberal. The name *Dendrochilum*, which is frequently used in connection with these plants, belongs more correctly to an allied genus.

House-plants for Shady Windows.

IN the effort to establish a window-garden various disadvantages are encountered, not the least of which is found in adapting to this purpose a window which enjoys little or no sunshine, although such windows are sometimes the only available ones. This naturally makes the selection of the plants more difficult than where all the advantages of full sunlight are enjoyed, but still it need not discourage the window-gardener, for a very pretty mass of greenery, as well as some flowers, can be grown, even under these conditions.

As might be expected, foliage-plants will occupy a prominent place in a window arrangement so situated, and at the head of the list of suitable subjects should be placed the *Aspidistras*, plants which possess such vitality that sunlight seems a secondary consideration. Either of the varieties of *Aspidistra* will be found satisfactory, though *A. elatior* and its variegated form are the best, the latter being generally more dwarf in habit than the type, and, like it, in needing repotting only at long intervals. The *Begonias*, also, are shade-loving subjects, and the beauty of foliage and flower combined in this extensive genus gives considerable variety from which to choose for the window-garden. The *Rex Begonias* are invaluable for this purpose, their massive many-tinted leaves adding much to the effect, and *B. metallica* is also excellent, being a strong and rapid grower, and pretty both in foliage and flower. *B. nitida* is another handsome, strong-growing species with large glossy green leaves and panicles of rose-colored flowers, while *B. rubra* makes an admirable companion plant for the above, its flowers being very large and bright red. If still more variety is needed among the *Begonias*, we may add *B. Saundersii*, *B. semperlorens* and *B. manicata*, for, though the latter sort is a cropper in blooming, yet it is so graceful and pretty when in flower as to be a general favorite.

Calathea zebrina can also be safely recommended for a shady window, though it should be borne in mind that this plant will not thrive if allowed to get very dry, nor in a room in which the temperature falls below fifty-eight or sixty degrees at night. A nicely berried plant of *Ardisia crenulata* will do much to brighten the window-garden, its glossy leaves and bright red berries reminding one of Holly, without the prickles. It is advisable, however, in getting plants of *Ardisia* that they should be not less than five-inch-pot size, as they seldom bear berries before that size, and it should also be remembered that they cannot endure defective drainage and stagnant moisture at the root.

Fatsia Japonica, or *Aralia Sieboldii*, is another good subject for the window, and will flourish in spite of draughts and lack of sunshine, its large deeply lobed leaves of dark green being very ornamental, and, for variety, one or more of the variegated forms may be added, though these may not prove to be quite so hardy as the type. *Clivea miniata* is another excellent house-plant, its strap-shaped leaves being evergreen, and the strong spikes of orange-flowers will appear at indefinite times

throughout the year. This plant is very easily grown, and requires no more care than an *Agapanthus*, though it is rather more tender than the latter, and, like most of the *Amaryllids*, needs a certain degree of rest previous to flowering, but not absolute drying off.

The Bow-string Hemp (*Sansevieria Zeylanica*) is also a plant of accommodating habits, and will flourish in the shade, while the dust and dry air of a living-room seems to have but little effect on it. It has long, narrow, erect leaves, the ground color of which is dark green, curiously mottled with grayish white.

The dwarf Papyrus (*Cyperus alternifolius*), and also its variegated variety, may be used with good effect, the most essential point in their culture being an abundant supply of water.

Peperomia maculosa is a pretty little plant with thick fleshy leaves that are marked with silvery variegation, and should be grown in small pots or pans with an abundance of drainage material, since it is essential to the welfare of this plant that it should not be overwatered, especially during the winter.

Some Palms may be used for a sunless window, for, while most of them are improved by a measure of sunshine, yet it is not absolutely essential for all, and among those best adapted for the present purpose are *Kentia Forsteriana*, *K. Belmoreana*, *Rhapis flabelliformis* and *Livistona Chinensis*, all of which will flourish with reasonable care. From the Ferns a number can readily be selected, those having fronds of firm texture being most reliable for household use, among these being *Polystichum acrosticoides*, *Pteris serrulata*, *Nephrolepis exaltata*, *Pteris Cretica* and some of the Maiden-hairs, *Adiantum Capillus-Veneris* and *A. cuneatum* being probably the most reliable of these.

For carpeting the surface of the soil in some of the larger pots *Selaginella Kraussiana* is useful, and makes a very pretty covering in a short time, and seems to enjoy the shade. The Variegated Periwinkle (*Vinca variegata*) may be put to good use in draping the plant-stand, for, while this handsome vine grows vigorously in the full sun, yet it may also be grown in the shade to entire satisfaction. All the plants thus briefly noted may be grown in any reasonably good loam, and, with proper care in watering, will make themselves thoroughly happy and at home.

Holmesburg, Pa.

W. H. Taplin.

Notes from the Harvard Botanic Gardens.

CURCUMA ROSCOEANA.—This interesting and highly decorative plant is a tuberous-rooted stove-herb, sending up in spring several elegant arching leaves with slender sheathing petioles from eighteen to twenty-four inches long, and oblong-oval blades of pale green color two-thirds the length of the petioles. The scape, twelve inches high, appears in summer, and the upper portion is a dense mass of concave, rich orange-scarlet bracts. The flowers are tubular, with two spreading lips about three inches in length and of light yellow color. They are produced singly at the base of the curved bracts, which enclose the lower part, leaving only the limb visible. The bracts retain their brilliant color for several months, but the flowers soon fade, though they are repeatedly replaced. *C. Roscoeana* is found on the coast of Tenasserim, in the East Indies, whence it was introduced in 1837. A moderately high temperature is necessary to its satisfactory development, and it seems partial to slight shade; the color of the bracts, at least, is longer preserved when the plant is grown in a shady position. It requires to be kept quite dry in winter, and the roots should be shaken free of the soil in spring and repotted firmly. A free supply of water is essential until the leaves begin to turn yellow, when it may be gradually discontinued. The roots are easily divided, and the plant is readily propagated by that process.

EUCHARIS GRANDIFLORA.—This plant, better known, perhaps, as *E. Amazonica*, or the Amazon Lily, is an old tenant of our stoves, but it is none too common nowadays. The mite (*Rhizoglyphus echinopus*), which worked such havoc among the bulbs a few years ago, influenced many in parting with the plant, and deterred others from beginning its cultivation. Little complaint is now made of the insect, and the plant should be restored to favor. The pure white, drooping flowers, of heavy substance and four inches in diameter, are borne in large clusters at the top of erect scapes two feet high. It is seldom that more than two or three blooms are fully developed on a single scape at the same time; but they open in such constant succession, and the scapes are produced in such profusion, that the plants form most pleasing objects for weeks together. There is nothing more effective than the contrast between the luxuriant leaves and chaste flowers of

this plant, and the flowers have the further advantage of an extremely grateful odor. They are produced at various seasons, more abundantly in winter than at any other time, and the plant delights in moderate activity throughout the year. It should be grown in large pots or pans, placing a quantity of the bulbs four inches apart in each, and the soil should consist of rich turfy loam, fibrous peat and thoroughly decomposed cow-manure in equal parts, adding a small amount of lumpy charcoal. Perfect drainage is of primary importance, for the *Eucharis* requires a large supply of water, and frequent repotting is not advisable unless the plants are in poor health. They may be safely expected to bloom every three months, and for a fortnight before the buds expand, manure water may be administered every other day.

Cambridge, Mass.

Correspondence.

Fructification of the Grape.

To the Editor of GARDEN AND FOREST:

Sir,—Many of our varieties of Grapes occasionally bear defective clusters; some of the berries remain green, and not larger than bird-shot, throughout the season, while other grapes of the same bunch grow to full size and maturity. This imperfect ripening has been ascribed to deficiency of pollen, and it is advised to plant in the vineyard a few pollen-bearers—"male vines"—to provide for this deficient element of fructification. By many viticulturists this abortion of fruit is accounted for by "the reflexed stamens" in certain sorts of Grapes, these organs bending outward and downward away from the pistil, and thus failing to impregnate the stigma.

These explanations seem plausible, but further notice of this imperfect fructification makes me question their soundness. The reflexed stamen is natural to the *Riparia* Grape and to its relatives. The more frequent examples of this defective fruitage may be seen in the pure *Riparias*, yet even here there are exceptions, notably in the *Clinton*, which with me forms perfect clusters. The *Concord* Grape (a *Labrusca* with erect stamens) never shows this imperfect fruitage. On the contrary, the *Ives* (also *Labrusca*, with erect stamens) is often thus afflicted. The crop of *Ives* in 1890 was characterized by numbers of these aborted grapes, while in an enormous fruitage of the *Ives* in 1892 all of its berries developed to full maturity.

In capriciousness of fructification, however, the *Iron-clad* Grape is especially puzzling. It is a natural hybrid between *V. Riparia* and *V. Labrusca*, with reflexed stamens. Soon after I first fruited this Grape, in 1876, I exhibited samples of it at the Centennial Exposition. Each lateral then bore five or six perfect clusters, the berries all fully formed and matured. The vines bearing this fruit were nearly as densely crowded with clusters in autumn as they were with foliage in summer. They were planted in a block of a thousand vines, all the one variety, set six by nine feet apart. Their wood-growth was rampant, single stocks making in one season several canes each from twenty to thirty feet long, with luxuriant lateral branches. Pruned in the same manner as were the *Concord* and *Ives*, on the so-called renewal system, that is, with two canes, with six buds on each, these *Iron-clad* vines as they grew older began to set imperfect clusters, and in a few years it was difficult to find half a dozen fully developed berries on a cluster, all the rest being little green abortions, clinging to the stem, and thus remaining throughout the season. I then left one row of these vines unpruned; these fruited full of nearly perfect clusters, while the vines in the pruned rows gave the usual defective bunches.

In close vineyard culture this non-pruning method is hardly practicable, and I tried the plan of letting a few vines run along the trellis as far as they might grow, their laterals being spurred to one bud. Near the extremities of these long canes the clusters were full and perfect, while near the stock they were made up of chiefly aborted berries. As the reflexed stamen is a constant character of this variety, if such stamens are the cause of abortive berries, this defect should have been seen in all the clusters.

The behavior of the *Ives* Vine in this respect is also perplexing; having erect stamens, why should it sometimes bear imperfect scraggy clusters? The evidence apparently contradicts the theory. Years ago, to test the *Iron-clad's* ability to resist the black-rot, I planted many of these vines along a trellis intermediately with *Concord*s, the vines of both sorts intermixing on the wire. Growing thus the *Iron-clad* annually fruits bountifully, with perfect clusters. It might be argued that here the *Iron-clad* blossoms are impregnated by pollen from those of the *Concord*; but, unluckily for the force of this reasoning, the blossoming of the *Iron-clad* is over, and its fruit

is formed before the Concord flowers are opened. There is an interval of ten days between the blossoming of the two. It is certainly remarkable that the only old Iron-clad vines on my farm which bear annually full crops of perfect bunches are those growing interspersed with vines of Concord and of Ives. Remarkable, too, that the same is true of those which are left to grow without pruning. I have planted Iron-clad vines at the foot of each Apple-tree in my orchard, letting them climb as they will through the tree-branches. Thus growing they fruit perfectly, in spite of the reflexed stamens. We know that pollenization is essential to fructification, but it is by no means certain that all Grape-blossoms which have both stamens and pistils may not always be competent to their own impregnation, notwithstanding the reflexed form of the stamens. These organs are not reflexed until the cap is shed from the blossom. I am assured by an eminent botanist that "the Grape stigma is certainly pollenized from its stamens before the cap falls from the flower." Hence the theory that pollen-bearing vines, male vines especially, should be planted in the vineyard to aid fructification seems unsound. For some fifteen years I have practiced on this theory, growing pollen-bearing vines scattered through my vineyards, yet I have never seen results from so doing which might not be as well ascribed to other causes. I suspect that a full fructification of the Grape-vine is greatly dependent on the nutrition of the plant, on accidents of the season and on the sterilizing influence of sundry fungus germs. Since I have been making experiments in vegetable pathology I think I have seen a marked benefit to fructification by spraying the vine when in full bloom with the Bordeaux mixture.

It has been suggested that for the development of the pulpy or edible part of the fruit the normal development of the seed is essential, and that, therefore, elements of plant-food which largely contribute to the growth of the seed, notably phosphoric acid and potash, should be supplied. It is true that the portion of my vineyard where the fruiting of the grapes with reflexed stamens was heaviest had been heavily treated with superphosphate of lime. Against the plausibility of this theory stands the fact that good seedless apples and pears and other fruits are not rare.

The sum of the matter is that the process of fertilization is not yet fully comprehended, and that we are still far from a scientific solution of many of nature's mysteries.

Vineland, N. J.

Alex. W. Pearson.

Roses in California Without Irrigation.

To the Editor of GARDEN AND FOREST :

Sir,—Two young ladies of Oakland, who conduct a Rose-nursery here, grow their stock from cuttings of mature wood taken in the latter part of autumn or in winter; these are put as soon as possible into nursery-rows where they are to grow. The rows are far enough apart to admit of cultivation with a horse. It so happened last winter that the cuttings could not be planted until well into February. For the most part they rooted well, and at once commenced a vigorous growth. In May the plants of La France, of which a large stock was put in, commenced to bloom just one month later than the plants from which the cuttings were taken. They have bloomed continuously ever since, yielding an almost incredible number of good commercial flowers. Duchesse de Brabant and Papa Gontier follow pretty closely after La France in floriferousness, but up to the present time no other kind equals La France. It is remarkable that from May to the middle of October these plants grew and bloomed without irrigation or rain. This statement seems almost incredible, even to Californians, but it is entirely true, nevertheless. The climbing sorts have made, in many instances, a growth of five and six feet. A row of Claire Carnots, another of Estella Pradels, and still another of Madame Alfred Carrières have sent up shoots the size of one's finger, and in the early part of November they were blooming quite freely. Perhaps 200 other sorts are doing equally well after the habit of each. Of course, these Roses are well cultivated, and this experience is a confirmation of my belief, often stated, that Roses will do well without irrigation on any land where an orchard will thrive, provided they have good cultivation.

I am frequently asked to name the twelve best Roses for our locality, and have made the attempt perhaps fifty times with as many different results, but in every list La France stood at the head—a place it is likely to hold for years to come. The red sport, Duchess of Albany, promises to stand pretty closely alongside the parent sort, but it seems a little weak yet from overpropagation, no doubt, and besides has by far too many imperfect flowers. A few years' propagating, by means of

strong-selected cuttings from mature wood, will, no doubt, create a greatly improved strain of this race. The same will apply to Waban, the red sport from Catherine Mermet.

Oakland, Cal.

H. G. Pratt.

New Cyripediums.

To the Editor of GARDEN AND FOREST :

Sir,—The following Cyripediums have recently flowered at the United States Nurseries, Short Hills, New Jersey :

CYRIPEDIUM LUTESCENS.—This is the result of crossing *C. Spicerianum* with *C. Javanicum*. Leaves broad, rather long, thick, pointed, light green, beautifully tessellated with dark brown, with silvery cast underneath. Flower large, well proportioned; dorsal sepal large, recurved at the base, yellowish green, with few faint lines of darker green. Lower sepal small green; petals yellowish green suffused with lilac at the ends and spotted all over with very small brown purple spots. Lip large, rather long, green, shaded with brown; staminode of a beautiful lilac color.

CYRIPEDIUM LEEANUM PULCHELLUM.—A cross between *C. insigne Nilsoni* and *C. Spicerianum*. Leaves rather narrow, growth more compact than the type. Flower large, dorsal sepal recurved, dark green at the base. Petals drooping, spotted all over with small spots and margined with yellowish green. Lip large, heavily shaded with brown; staminode of a beautiful lilac color.

CYRIPEDIUM LEEANUM LUTESCENS.—A distinct type of *C. Leeanum*, on account of its yellowish green color, derived from a yellow variety of *C. insigne*, one of its parents. Flower large, well formed; dorsal sepal yellowish green at the base, with a few faint lines of spots of a light purple. Sepals and lip of the same color, slightly shaded with brown and spotted with brown-purple.

Short Hills, N. J.

Jos. Manda, Jr.

Plant Labels.

To the Editor of GARDEN AND FOREST :

Sir,—With reference to the article in your issue of August 24th, I beg to state that the labels alluded to are manufactured by the Fabrik der Universal-Etiquetten, 5 Winkelried Platz, Bale, Switzerland. The ink is a marking ink, such as is commonly used for marking linen. These labels are neat, clean and very durable; but their great drawback is that the writing upon them must be done with ink and that they can be used but once, because this lettering cannot be effaced. Wooden labels painted white or yellow, on which one can write with a pencil, are still preferable, if they are made from wood felled in winter and seasoned for a year; but nowadays they make these from timber felled at any season of the year, and such labels are subject to fungus, which they communicate to the soil, and which is often destructive to delicate plants. Besides, wooden labels must be replaced and renewed in writing after a year or so.

I have used in the boxes where I keep my rarest plants glass labels, with good results. They are made of milky glass, which is dipped in some acid to take off the gloss and thus produce a soft surface, which is very agreeable to write upon. Characters traced with a hard pencil stand the weather well, and the labels look like porcelain, and are perfectly clean. By rubbing with emery-paper, sand and water, the writing can be perfectly effaced and the label used again. This form of label, too, has one great disadvantage—that is, a brittleness which makes it very liable to break.

What is wanted, especially for amateurs, public gardens and botanical establishments, is a label of some mineral material with a smooth surface, easy to write upon, of a pale or whitish color, which shows off the writing to best advantage; it must be possible to efface the letters somehow, and it must not be broken easily. Such a label might be made if inventors and manufacturers could only be brought to interest themselves in the matter.

Baden Baden.

Max Leichtlin.

The River Garden at Coblenz.

To the Editor of GARDEN AND FOREST :

Sir,—The article in your issue of November 23d on the Rheinanlagen at Coblenz might have said much more of the great beauty of that garden without risk of overpraise, and its value to the city cannot be too highly estimated. I remember an exceptionally hot June morning there, a few years ago, when one thoroughly appreciated the facilities which the Anlagen offered for a shady stroll or quiet reading as one sat

near the river-bank, sheltered from the glare, but just able to catch the fresher air from the water. In an average American town of the same size one would have gone, not to a garden, but to the station, in order to get away as soon as possible, and the transient population would have consisted merely of those who could not get away. It would be interesting, from a practical point of view, to estimate the gain to the business interests of Coblenz from the influence of the Anlagen in inducing strangers to stop off and not to hurry away. It would be more interesting, from a philanthropic standpoint, to estimate the gain to the physical and mental health of the Coblenzers—to their life, in the fullest sense—from this ideal utilization of a part of their river-front.

The Beauties of Nature. By the Right Honorable Sir John Lubbock, Bart., M.P., F.R.S. New York: Macmillan & Co.

The subtitle of this volume, "The Wonders of the World We Live In," will perhaps more truly describe it than the words which appear on its cover, for the objects in the natural world which make the strongest appeal to our sense of beauty are not those chiefly discussed. There is an introduction of some forty pages, it is true, wherein the power of scenery to soothe and elevate is touched upon, and wherein we are treated to some descriptions of the quiet beauties of English landscape by Jefferies and Kingsley, while Humboldt is allowed to rhapsodize on the sublimities of a tropical night, Darwin is quoted to show the impressiveness of the boundless wastes of Patagonia, Professor Colvin writes of the chastened beauty of the scenery of Greece, and Wallace tells us how keen is the enjoyment which comes from color in sky and earth and water. But after this the reader finds little about beauty or any other single quality or phase of nature, for there is no pretense of any unity of purpose and hardly any connection of thought between the successive chapters or even between successive pages or paragraphs. It is not to be assumed from this that the book will be found uninteresting. The fifty pages devoted to plant-life treat in a pleasant way of some of the striking facts in the development of vegetation which botanical science has brought to light, and rather more space is given to the history and characteristics of a very small fraction of the two million or more species which make up the animal kingdom as it exists, not to speak of as many more that are extinct. Then we have a chapter on the Starry Heavens, with some account of the ordering of the countless hosts which wheel through infinite space. Still another chapter is devoted to the sea, with the mystery of its depths and the majesty of its swelling surface; another to the mountains and the forces which have lifted them up and are wearing them away; while yet another tells the story of the lakes and rivers, whence they took their origin and what directed their waters as they channeled their devious courses to the sea. The entire universe, with its history through unnumbered æons of astronomic time, is thus laid under contribution, and there seems no reason in any given instance why Sir John has selected one topic out of any given million, or why he has chosen to treat it in a particular way.

Of course, when astronomy, geology, botany, zoölogy and many subordinate branches of natural science find a place in a single volume, no subject can be exhaustively or comprehensively treated, but, after all, it may be said that the science is genuine. Unlike many other attempts to cast in popular form the results of learned research, the facts are stated with accuracy and clearness. Young people especially will find much in these fairly printed and attractively illustrated pages to give that pure delight which accompanies the widening of the horizon of their knowledge, and the bright boys and girls into whose hands they come cannot fail to have their attention arrested and their spirit of investigation stimulated.

Periodical Literature.

Most of our colonial towns have been made familiar to the present generation by repeated descriptions and illustrations. But, for some reason, Annapolis has not excited the same amount of attention. It is pleasant, therefore, to find, in a recent number of the quarterly *Architectural Record*, a delightful historical and descriptive account of it, written by Mr. T. Henry Randall, who was born within its verdant borders, but is now an architect of this city.

Essentially a countryman by preference, says Mr. Randall, the early colonial American of the southern states "loved

above all things the comparative solitude of a great country home. When, however, his business or profession required him to live a part of the year in some town or city, we find, as a rule, the same general plan for the house followed as in the country; and the small allowance of room for garden, surrounded by a high brick wall, is laid out with the evident purpose of making it as secluded as circumstance would permit." In Annapolis this type of house and garden was developed better than anywhere else. "On the peninsula at the mouth of the Severn River, nearly surrounded by exquisite sheets of water, the first colonists found an ideal site for a prosperous town, and between it and the Chesapeake Bay a harbor which promised to give to it the commercial supremacy of the colony. Here they laid out their town, not at random, but with a fixed idea of making the most of all the advantages that the formation of the ground possessed, circumstances which, in later years, turned the tide of prosperity away from here and left this quaint old town almost unchanged for a century as 'the finished city of America.'

"From its infancy," Mr. Randall then explains, "Annapolis had a peculiar manner of development as unlike that of her sisters as their appearance differs to-day from hers. She did not begin with hurriedly built huts, scattered over the surface, that were transformed later into comfortable dwellings and arranged with order and symmetry; but from the very first her English colonists seem to have conceived a delightful ideal in the planning of their new city. As a starting-point, in the centre of the city, and upon the greatest elevation the peninsula afforded, they set apart a circle with a radius of 528 feet, which space was to be occupied by such buildings as were necessary for the officers of His Majesty's Government. To the west of this point they reserved another circle as the site of the church. From these two centres streets were laid out, radiating in all directions, and parallel with the river, and others were carried from the shores of the harbor to the opposite side of the city."

The House of Burgesses was built in the larger circle, and, when the seat of state government was hither transferred in 1694, the first state house was erected, while the first church was built in the smaller circle in 1699. A small area was reserved on the harbor for a dock and other commercial uses; and a triangular section of the city, connecting the state house with this area, was reserved for purposes of commerce and trade. Here small, closely built hipped-roofed dwelling-houses and large store-houses were built; and here, and in another district west of the church, the tradespeople lived and worked, while outside of these restricted limits they could do neither. An open area westward of the church was, indeed, reserved as a common for their enjoyment and use; but all the rest of the city, including almost the whole of its beautiful water-frontage, was given up to the residences of the more aristocratic citizens, the land being apportioned among them by the Lord Proprietor, some receiving the whole of one of the squares formed by the intersecting streets, and others one-fourth of a square. "Only a few houses," says our author, "have to-day their original terraced gardens leading to the water and overlooking the harbor and the creek, but these few are enough to give us a clear impression of what must have been the appearance of this charming old town when, in the height of its glory (1750-1776), its entire water-front, with the exception of the wharves and dock on the harbor, was lined with stately mansions surrounded by their gardens and partly hidden among luxuriant foliage. The houses were, as a rule, placed almost directly on the streets, with the walled gardens at the sides and rear. These gardens still show traces of the skill that was devoted to them. Covered porches were few and small, and piazzas were almost unknown to the early colonists. Shade-trees and arbors answered their purpose then, for our forefathers still adhered to their English habits of life, and it was left to succeeding generations to discover that this southern climate required marked alterations in the arrangements of their homes to secure perfect comfort and convenience."

We cannot here quote Mr. Randall's many detailed descriptions of these stately Annapolis homes, which are illustrated, moreover, by a large number of excellent photographs. But the buildings and gardens are dignified and attractive. Of "Acton," the homestead of the Murrays, he writes that it still has "splendid old trees, hedges, flower-garden and lawn stretching in all directions. The flower-garden itself, as we see to-day so often in England, is separated from the lawn by high hedges running down to the water's edge from the southern side of the house, divided into beds by curiously planned walks lined with Box." Of the Harwood or Lockerman House, built in 1770, he says: "The garden at the rear falls

gradually to the east. The old Box-borders of the flower-beds have long since overgrown the walks which they once followed, and are now great hedges, indicating still the landscape-gardener's plan as it originally existed." And of the Brice House we read: "The drawing-room is unusually beautiful, and commands an outlook over the entire garden." These extracts hint at the fact that the most important rooms do not lie, as we so often find them to-day, contiguous to the entrance. The street-front of the house contains the windows of the minor living-rooms and offices, while the state drawing-rooms and dining-rooms lie at the rear, facing the gardens, with windows and doors opening sometimes on stately porticos and sometimes directly upon the lawns and commanding the beautiful water-views. There is much instruction for the modern builder of detached houses in this varied series of beautiful pictures and their accompanying text, and they leave us convinced that much more would be afforded by an actual study of the town itself. Indeed, as we finish the article, we cannot but believe the author when he says: "Annapolis may still be called 'the finished city,' and those who love her quaint old streets, her well-shaded gardens and her dark red walls of brick, can see in them something which no other city in this land affords." And, regretting that his city has been so long neglected in favor of others less worthy of attention, we are doubly grateful to him for thus bringing it to our notice. But now we wish that some adept in the art of gardening would follow in Mr. Randall's footsteps and speak as fully of the surroundings of the old homes of Annapolis as he has spoken of the houses themselves.

Notes.

Professor Budd says that sheep are not as a rule destructive to orchards, but, on the contrary, they are efficient in keeping down insects. They only eat the bark of trees when the bark is the only obtainable green thing.

A Louisiana correspondent of the *Florida Times-Union* states that *Citrus trifoliata* is very satisfactory there as a hedge-plant, making an impenetrable barrier against man and beast, and occupying less space than one of Osage Orange or the Cherokee Rose.

Among the supplies now found in New York markets are strawberries from California at \$1.75 a quart, Black Hamburg grapes from English hot-houses at \$2.50 a pound, hot-house tomatoes from Boston at \$1 a pound, new chicory from Louisiana at 20 cents a head, and fresh string beans from Florida for as much as customers can be induced to pay.

Dr. B. D. Halsted, of the Experiment Station at New Brunswick, New Jersey, is preparing a paper on diseases of the Carnation, to be read before the next meeting of the American Carnation Society, and he desires all persons who have any trouble with rusts or blights of that plant to send him affected specimens, so that he may be able to treat the subject as comprehensively as possible.

Dr. H. D. Warren, State Ornithologist of Pennsylvania, is preparing an exhibit of the fauna of that state for the Chicago Exposition. The foundation for this exhibit is the section of a mountain-side thirty-five feet long, twenty feet deep and eighteen feet high, and among the trees and undergrowth natural to an Alleghany forest-scene the birds and animals will be displayed in life-like positions and with their natural environment.

Mr. D. Nichol writes to the *Canadian Horticulturist* that the White Pine grows more rapidly on poor land in Canada than any other coniferous tree. He instances mixed plantations where White Pine trees have grown to be fifty feet high in twenty-two years, with every tree as straight as a mast, and this growth has been attained on poor land without any cultivation beyond thinning out the trees as they grew large and clearing away decayed under-branches. No other kind of forest-trees does so well when grown so closely.

Eulalia gracillima univittata is one of the most graceful of the noble hardy grasses, and its beauty and usefulness in the garden have become well known. It does not seem to have been noted that its ripening stems and leaves in autumn take on fiery brown tints, so that bold clumps of it are luminous objects in the garden till winter sets in. This coloring is peculiar to this variety, the other kinds simply fading out as they ripen. Like other *Eulalias*, this is furnished with the plumes which are the most graceful of those borne by any of the grasses.

The Massachusetts State Board of Agriculture has issued another edition of the descriptive catalogue of abandoned

farms, from which it appears that of the 339 farms originally advertised fifty-one have been sold, the owners of twenty-two others wished to have the description withdrawn, 178 owners wish the description continued, while there are eighty-eight farms from which nothing has been heard. But few of the farms disposed of have been taken for summer residences, the greater number of purchasers being Massachusetts men. The farms sold averaged 88.35 acres each, and brought altogether \$75,550, or an average of \$1,480 each.

A writer in the *Southern Stockman* says to test the ripeness of a Water Melon, the thumb-nail should be drawn over it so as to scrape off the thin green skin. If the edges of the skin on each side of the scar are left ragged and granulated, and the rind under the scar is smooth, firm, white and glossy, the melon is ripe. If the edges of the scar are smooth and even and the nail plows into the rind in places and the skin does not come off clean, then the melon is green. Two melons, one known to be ripe and the other green, should be taken and this test practiced on them until the difference is plainly observed.

After his address on orchard fruits, delivered before the Massachusetts State Board of Agriculture a fortnight ago, Mr. J. H. Hale, who is perhaps the most successful grower of peaches in New England, replied to a volley of questions from his auditors. The off-hand answers were quite as good as the address, and we add a few of them. Peaches should be fed with chemical fertilizers only. We apply every year all we can afford, that is, about 1,200 pounds of bone and from 400 to 800 pounds of muriate of potash to the acre. Too much is better than not enough. Sulphate of potash gives the best color to peaches, but cotton hull ashes is perhaps a better form of potash. Yellow-fleshed peaches have more tender fruit-buds than other kinds. We shorten in the new wood from one-third to one-half in the spring when the fruit-buds begin to swell. We can get a good peach crop with 90 per cent. of the buds winter-killed. After the fruit is set for a full crop we thin until there are no two peaches within from four to six inches of each other. This is a costly treatment, but it pays. The extras sell for six times as much per peach as the seconds do, and they do not exhaust the tree as much. The finest fruit this year came from fourteen-year-old trees. An elevated plain is not as good for a Peach orchard as a hill-side with a sharp decline. The fruit should be fully mature, but not mellow, when it is picked. Pickers are trained to judge ripeness by color. Peach-orchards should not be cultivated after the middle of July.

John Strong Newberry, professor of geology in Columbia College, died last week at Windsor, Connecticut, in his seventieth year. Professor Newberry was born in Windsor, Connecticut, in 1822 and was graduated from the Western Reserve College in 1846; then, after studying medicine at the Cleveland Medical College, he devoted two years to travel and study in Europe, and later established himself as a physician in Cleveland. In 1855 Dr. Newberry, in order to gratify his taste for science, obtained an appointment as Acting Assistant-Surgeon in the United States Army, and accompanied the expedition under Lieut. R. S. Williamson which explored the territory lying between San Francisco and the Columbia River, acting as surgeon and geologist. In 1858 he was attached in the same capacity to the expedition which, under command of Lieut. J. C. Ives, made the first exploration of the basin of the Colorado River of the west. In 1859 Dr. Newberry explored the country bordering the upper Colorado and San Juan Rivers, and during the war of secession rendered important service to the army as a member of the United States Sanitary Commission. In 1856 he was appointed professor of geology in the School of Mines, Columbia College, the position he occupied at the time of his death. Dr. Newberry's scientific publications are numerous and valuable. They were principally devoted to geology, and of late years mainly to paleontology. In 1860 he published a catalogue of the flowering plants and ferns of Ohio, but his most important contributions to botany are found in the sixth volume of the *Pacific Railroad Reports*, in which is printed his report of the plants collected on the Williamson expedition, with remarks upon the geographical botany of the region traversed, followed by a description of the forest-trees of northern California and Oregon, a paper which contains the fullest and most exact information upon these trees which has yet been published. Professor Newberry's service to botany is commemorated in *Newberrya*, a genus of leafless Ericaceous plants, dedicated to him by Torrey, which he discovered in the Cascade Mountains of Oregon.

Co-operation against Insect Invasions.

IN an editorial article in our issue for September 28 we endeavored to show that the enormous losses every year to our fruits and farm crops, from the depredations of insects, made some concerted action necessary as a protection against these pests. No industry can endure a tax of ten per cent., and this is not an exaggerated estimate of the average loss which our farms and orchards suffer every year from this source. The loss is more than a purely commercial one, for insects and fungi not only destroy marketable products of the farm and the timber of the forest, but by ruining shade-trees and ornamental plants they deface the beauty of the garden and roadside, and in this way detract much from the comfort and pleasure of country life. In a letter referring to our article, Professor J. B. Smith, of the New Jersey Experiment Station, cited striking instances where serious loss could have been averted by timely and united work, and at the meeting of the New Jersey Horticultural Society last week he read a paper on the same subject from which we are glad to select some illustrative cases for instruction and warning.

In 1884 the Pear midge was complained of in an orchard near New Britain, Connecticut, where it had been introduced in Pear stocks imported from France a few years earlier. The insect had been growing with little observation until, in 1883, it took nearly the entire crop of the orchard. The next year, however, Professor Smith found the insect still confined to two adjacent orchards, as there were no other Pear-orchards within several miles. Dr. Riley, of the Department of Agriculture, read papers before fruit-growers' associations, warning all concerned that the insect would not remain fenced in these narrow limits, but would break out and spread over the country, and although he received votes of thanks for his "instructive address," no one attempted to arrest the ravages of the insect. Of course, the orchard of New Britain did not hold it long,

and in 1891 it had invaded the Hudson River Valley in injurious numbers, and in 1892 a neglected orchard as far away as New Brunswick, New Jersey, showed that half of the Lawrence and Bartlett Pear trees there were attacked, while a few individuals had invaded a neighboring orchard, one of the best in the state. Of course, the extinction of this insect is now impossible, and no one can tell how many thousands of dollars it will cost the pear-growers of the country to struggle with this pest in future. By co-operative action this particular invasion could have been checked at the outset, and only by co-operative action can immunity from its attacks hereafter be assured. No matter how alert and careful a fruit-grower may be, after the insect once enters a fruit, it is destroyed. He can only take measures after the injury is done to prevent a renewal of it another year. But his individual effort will be of little avail. The valuable orchard above spoken of lying near the neglected orchard, which is only a breeding-ground for the midge, furnishes a case in point. No matter what measures are adopted by the owner of the good orchard to prevent the development of the insect on his own land, there is nothing to hinder the midges from multiplying by myriads in the neglected orchard, and, when developed, hordes of them will throng over the line to attack the luscious fruit. It is the old story over again, the industrious and energetic man suffers from the lazy indifference of his thriftless neighbor.

The insect most dangerous to the Blackberry is the red-necked cane-borer, which lays its eggs at the axil of a leaf, leaving the larva to girdle the cane. In the effort of the plant to repair the injury the well-known galls are formed, and by simply cutting these out in early spring, when pruning, and burning the cut wood, the entire brood can be destroyed. But the careful grower clears his land to no purpose so long as the beetles will mature on his neighbor's canes, and then fly over to destroy his crop. Near Hammonton, New Jersey, there are many fields which are simply left to take care of themselves and every cane is infested. Such fields are simply nuisances. They will bear no fruit themselves and will produce insects to reduce the crop of all surrounding fields. Last year the crop in that vicinity was reduced twenty-five per cent. by insects alone, and next year the loss will be full one-half of the crop. It is another case where the shiftless husbandman brings ruin upon his neighbor as well as himself.

Now, it would not be difficult to draft a law which might protect a careful fruit-grower from the noxious insects bred by the recklessness of his neighbors. The difficulty at once arises that no such law will be enforced. There are similar laws against noxious weeds, but offenses against them are rarely brought into court. In California a law was passed which required the owners of Orange and Lemon-groves to use remedies which had been proved effective against the scale insect. Few persons obeyed the law, and when actions were instituted under the statute, juries of farmers could not be induced to convict the transgressors. In one of the north-western states, where swarms of Rocky Mountain locusts were devouring every green thing, it was shown that plowing over the ground where the eggs had been laid would destroy the insects and prevent injury the following year. The Legislature passed a law to make this plowing compulsory, and provided for having it done by the state where it was neglected. Still, a very small number of farmers obeyed the law, and some of them even demanded damages for trespass upon their land, when the work was done for them under state authority. It is better to enact no law than to pass one which remains a dead letter on the statute-book and thus helps to breed a contempt for all law. What is needed first in every case is an enlightened public opinion behind any given law, so that its enforcement will be ensured.

In another column of this paper will be found the instructive record of a campaign against the tent caterpillar

in a Massachusetts town. We have no doubt that there are individuals there who give no help to the enterprising societies which are fighting the insect and who make merry over the idea of a bug-bounty. And yet it is just such work as this which tells directly in helping to destroy insect pests in any given instance, and still more in showing how much can be accomplished by united labor for in this way public sentiment can be generated and developed into an efficient force behind future legislation. It is a very difficult thing to unite all the members of a community in any systematic action, even when the necessity is at their very door. It is almost impossible to secure the co-operation of land-owners throughout a state to prevent an evil which they do not see, and which they, therefore, do not dread. But, after all, union for protection is the only practicable way to meet these enemies. This is the first necessity, even if the best of laws are enacted.

The Cedar of Lebanon.

THE Cedar of Lebanon has stood for generations throughout Christendom as the type of all that is majestic and regal in a forest-tree. It has in modern times been questioned whether the timber with which Solomon rebuilt the Temple was that of the true Cedar, but, however this may be, the trees are always associated in the popular mind with stately religious ceremony, and the groves of Lebanon have been objects of veneration by pious pilgrims for centuries. The position which the tree holds in Christian literature is well exemplified by the following passage from the *Spirit of the Hebrew Poetry*, by Isaac Taylor, who, in describing the Lebanon ranges and their trees, says: "In ancient times these rich slopes and valleys were mantled with Cedar-forests, and the Cedar, in its perfection, is as the lion among the beasts and the eagle among the birds. This majestic tree, compared with others of its class, has more of altitude and volume than any of them, it has more of umbrageous amplitude; especially it has that tranquil aspect of venerable continuance through centuries which so greatly recommends natural objects to speculative and imaginative tastes. The Cedar of Lebanon, graceful and serviceable while it lives, has the merit of preparing in its solids a perfume which commends it when dead to the noblest uses. This wood invites the workman's tool for every ingenious device, and its odoriferous substance is such as to make it grateful alike in palaces and in temples." As a matter of fact, it would be difficult to exaggerate the impressiveness of this tree, even if it were not dignified and almost hallowed by association. In vol. ii., page 148, we have already given a figure of one of the old trees on Mount Lebanon, and in the same issue is an illustration of a pair of wide-branching old specimens, such as are to be found in many of the stately pleasure-grounds of England, where this Cedar has been more generally planted for the last two hundred years than any other foreign tree. In connection with the pictures, some account was given of the remnants of the Lebanon forest, as described by Sir Joseph Hooker, and the illustration on page 607 shows one of the nine groups which remain in one of those elevated valleys. Only 400 of the trees survived at the time of Sir Joseph's visit, and unless the seedlings are protected from fire and from sheep and goats, these particular forests will, in course of time, become extinct. The largest trees remaining are some forty feet in girth, and the smallest ones are eighteen inches. Other groups of this Cedar have been discovered since the visit of Sir Joseph Hooker, and, in fact, *Cedrus Atlantica*, which is found in Algeria and Cyprus, and *Cedrus Deodara* of the Himalayas differ very little in botanical characters from the true *C. Libani*, although they are quite distinct in appearance at all stages of their growth. For some unknown reason the Cedar of Lebanon has never been a favorite with American planters, although it is hardy in the latitude of New York, and the few specimens here which have attained the age of fifty years and upward are noble trees.

Notes of a Summer Journey in Europe.—XX.

THE late reconstruction and rearrangement of a large portion of the Arboretum at Kew is likely to give the idea of comparative newness, but there are old trees enough to impress one with a feeling that the establishment has reached a venerable age. For the most part, the specimens, both young and old, are in a vigorous condition; and, it is hardly necessary to add, the correctness of the labeling can be more safely trusted here than in many of the institutions on the Continent. A notice of a few of the specimens and groups may give a faint idea of the collections as a whole. The Oaks may be counted as forming one of the largest generic groups, being represented here by over two hundred species and named varieties. Of the so-called varieties fifty or sixty are forms of the two English or European Oaks, *Quercus Robur* (also known as *Q. sessiliflora*) and *Q. pedunculata*, by far the largest number of these forms being referable to the latter species. *Q. pedunculata* itself is still classed as a natural variety *Q. Robur* by many botanists. Of course, most of these fifty or sixty named forms have originated by selection and long cultivation, and can only be propagated by grafting or other modes of division.

There is a good series of the more hardy American Oaks, by far the best specimens being those which come under the black or biennial fruited section of the genus. The American White Oaks, both in England and on the Continent, for some unexplained reason, do not seem to thrive as they do in their native country. One of the finest examples of the American species is a specimen of the Willow Oak (*Quercus Phellos*), with a trunk over three feet in diameter, and a spread of branches of at least sixty-five feet. This specimen has apparently reached its best development, for a fungus is beginning to show itself in places in the bark. Our Scarlet, Black, Red, Pin (*Q. palustris*) and Laurel (*Q. imbricaria*) Oaks all thrive well here, and some of them are said to show fine autumn colors of foliage.

Of other exotic species the Turkey Oak (*Q. cerris*) and its forms seem admirably suited to the soil and situation at Kew, the branches of the largest specimen seen here spreading about a hundred feet, the trunk being fifteen or sixteen feet in circumference; while *Q. conferta*, a native of south-eastern Europe, impressed me as being one of the handsomest and most satisfactory of all the species in the collection. A specimen here which gave evidence of very fast growth had a broadly conical outline, large and abundant foliage and a trunk about twenty inches in diameter. The oaks, as well as most of the other trees, appear to be pretty accurately named on the whole, and show the active care and interest taken in them by Mr. Nicholson. The nomenclature of the Lindens, however, is sometimes puzzling, as it is in most collections.

Among other deciduous trees notable for their age or size, examples of *Sophora Japonica* are likely to attract attention, especially when they are in blossom. One of the largest of these is about fifty feet in height and thirteen or fourteen feet in circumference of trunk. At a few feet from the ground it divides into several very large limbs, which, at about twenty or thirty feet from the ground, are held from breaking or unduly spreading by strong iron chains and encircling iron rings. I was surprised to see this system of supporting weak limbs in practice at Kew, for the iron rings, having been on for many years, were deeply embedded in the bark and wood, and the limbs were evidently slowly and surely being choked to death, and the beginning of the end was shown in large dead branches which workmen were removing. A bolt fitted with a ring or eye at the head, to which to fasten connecting chains or rods, and put through a hole bored in the limb just large enough, is much to be preferred to a ring around it, even though it may be quite loose. The new bark and wood tissue will soon close up the entire space about the bolt, and so prevent the ingress of fungi or other diseases, and the small hole necessary for the reception of the bolt does not materially weaken the limb, certainly not nearly so much so as a band or girdle does after it begins to cause a constriction of the part under it. This ring or band system is very commonly used, and it is often pitiable to see the poor trees endeavoring to overcome the obstruction to the free circulation of its sap by swelling and extending its tissues over the unyielding girdle.

A tree which attracted my attention was an unusually fine specimen of a Hop Hornbeam fifty feet in height, branching near the ground and spreading about seventy feet, and with a trunk over three feet in diameter. It is labeled *Ostrya carpinifolia*, a native of south-eastern Europe. This specimen is grafted on stock of a Hornbeam (*Carpinus*) at about two and a half feet above the ground, and it is a good deal larger than its stock, and has a swelling at the point of juncture. No one can

help remarking the striking contrast between the rough bark of the *Ostrya* and the dark-colored, comparatively smooth bark of the *Carpinus*. Other such interesting trees are not rare here, but many or most of them are equalled or surpassed as specimens by examples in gardens in various parts of the kingdom.

The collection of hardy conifers is quite large and varied as regards numbers of species, and it possesses a good deal of interest to the specialist in this division of dendrology. But while such species as the *Gingko* seem to thrive very well, the evergreen conifers must suffer from the great volumes of smoke which sometimes settle over the gardens. This smoke not only proves a great handicap to the production of good conifers, but also operates against other evergreens of the Angiospermous class, and it is a source of great annoyance by sometimes settling and covering the great glass-houses with a thick black dust, which is so persistent and adhesive that it is necessary to wash the glass carefully after some especially severe visitations. If in summer the old leaves of an evergreen plant are rubbed, the persistent black dust will readily come off on the fingers. The proximity of factories and of a great city where soft coal is used is thus a serious drawback to the successful growth of a great variety of evergreens, and as it does not seem likely that this can be ameliorated at Kew such trees as most evergreen conifers will always find this an obstacle in the way of their highest development. This does not mean that such conifers cannot be grown here, for they can be, and are, and the collection at Kew is both large in number of species and interesting in regard to the size which some of the specimens have attained, although, perhaps, few of them are so large as most people would expect to see them.

Possibly it is on account of their being in the midst of this seething multitude, with its gases and coal-smoke, that the Big Trees, or *Sequoia gigantea*, introduced from the California groves, appear to be degenerating after a good many years of active and promising growth, and after attaining proportions of a fair-sized tree. At first the *Sequoia* has a fine symmetrical form, but after it attains a height of thirty or forty feet it is liable to become ugly by the loss of branches and a general straggly appearance. Although there may be peculiarly favorable spots in England where the trees may enjoy a life of many centuries and become of large size, their chances for any such development near London seem very slender; and this can hardly be wondered at if we but compare the atmosphere in which the foliage is often placed now with the high pure air which was its element for centuries in its aboriginal surroundings. This is one of our American trees which, although it can be grown in Old England, will not thrive out-of-doors in our cold New England climate. It is gratifying to know that the common name of *Wellingtonia*, which this noble tree early received in England, seems to be giving way to its proper title—*Sequoia*. A so-called "weeping" form of this tree is now in cultivation in some foreign nurseries.

The Pines here generally appear quite healthy, and there are some very fair examples of several of our American species. Among these are *Pinus Coulteri*, over twenty feet high and bearing cones; *P. contorta*, twenty-five or thirty feet high and also fruiting freely; the dwarf Gray or Jack Pine (*P. Banksiana*), of our far north and north-west, looking healthy, but as straggly as on its native soil; and an example about nine feet high of the odd so-called One-leaved Pine (*P. monophylla*) with its leaves both single and in pairs. In another portion of the garden there is a specimen of *Pinus Sabiniana* with a trunk nearly two feet in diameter and a much larger and handsomer example of the Corsican Pine.

The North American Spruces show much variability between species as to their adaptability to the situation here, and the Himalayan *Picea Morinda* seems to thrive much better than some of them. This is a species which is not adapted to our New England climate, but it is a desirable tree, having long leaves and long slender branchlets, with the drooping habit of the Norway Spruce. Some of the Hemlocks seem pretty thrifty, but the Junipers are not very satisfactory although some dwarf species seem to do better than others.

Most visitors are interested in the specimen of Chili Pine, or "Monkey Puzzle" (*Araucaria imbricata*), grown in the open air here, but only known to us when brought under warm shelter in winter. This oldest specimen at Kew was planted in 1796, so that it is very nearly a hundred years old; but it has not attained the size of younger plants in other places. It was one of the first plants introduced, and for many years after its reception at Kew it was grown in a greenhouse as we would a Palm. It was, afterward planted in the open ground, but protected in winter, until it was demonstrated that it was quite hardy in the English climate. It is now only about thirty-five feet high, with a trunk fifteen or sixteen inches in diameter.

The Japanese *Gingko* is here a thrifty tree, as it appears to be in most places where it has been tried. It is likely to become much more popular, but we do not yet know how it will bear old age in this country.

Arnold Arboretum.

J. G. Jack.

On Broad Top.—II.

BROAD TOP was beautiful this autumn in an unusual way. The passing of summer was so gradual that at one time it seemed as if winter would find the Maples still green, and a flurry of snow on the 5th of October found them but slightly tinted. They seemed to be eclipsed by the wonderful tones of color shown by the Tupelos, Oaks and Hickories; but the snow turned to rain, and after two days of that, when the curtain of mist rolled away, the Maples suddenly appeared in their old-time splendor.

For the first time in our recollection some of the streams and springs became dry, but, in spite of this, the Ferns and water-loving plants were never more fresh and fine. The Cardinal-flowers seemed unable to end their brilliant life, the *Chelones* were crowded with blossoms, and the closed *Gentians* were remarkably numerous and beautiful.

Before the mountain itself showed more than faint touches of color there was a short-lived, but brilliant, display made by a forest-surrounded meadow lying at the lower extremity of this little farm, now our temporary home. The farm, and most of the surrounding mountain, forms part of a 12,000-acre tract belonging to one of the coal and iron companies, and as all the most beautiful country here is in the possession of corporations, no private holdings are possible.

While this farm by no means belongs to the class of "abandoned farms," the fields lying between the house and meadow are object-lessons in the relapse from cultivation to original conditions. Passing down through the fields, we find the uppermost one, which always is in fairly good cultivation, in Clover. The adjoining field has the same starved, slaty soil as the next below, and the two are separated by a fence overgrown with vines and shrubbery. Only a small portion of both is in cultivation, now planted with Corn, Potatoes and Buckwheat; the rest of the thin soil shows a faded growth of Golden-rod. A tree-bordered fence runs along the lower side, and beyond it lies the largest field of all, once like the others, with infinite labor cleared from out of the forest. Now the sparse grass on its sloping surface is covered with a mat of Creeping Blackberry, Asters and Golden-rod, and in the field-corners are thickets of young Maple, Hickory, Yellow Pine, Cucumber and Locust trees.

The meadow which is our destination, though close by, is not visible, as its fence is concealed by a dense growth of Oak, Sassafras and Witch-hazel. Midway in this hedge, a broken panel of fence gives access to the meadow, and from this gateway, framed by two Oaks, the whole scene, an enchanting harmony of color, is before us. The meadow, almost circular in form, is an expanse of silver-green marsh-grass, forming the foreground for brilliant masses of shrubbery, thrown into relief by White Pines on the edge of the forest beyond. In the near foreground lie a couple of crumbling Chestnut-trunks, almost buried in bracken; beyond them is a most effective little island of sedge, and the entire meadow floor is thickly dotted with such quantities of *Spiranthes cornua* as I have never found elsewhere. The shrubbery crowding every little point of dry land which projects into the marshy grass gives a distinctive character to the place. Almost every species found on the mountain is represented here; most notable for form and coloring are the wild Crab-apple and Thorns. Between the shrubbery and encroaching forest lies a crowded mass of plants, interesting now, but infinitely more so in the spring.

In a cursory examination of a space about ten feet square, I noted closed *Gentian*, Golden-rod, wild Parsnip, Wintergreen, *Arbutus*, three varieties of Ferns, several of Grasses, two each of *Lycopodium* and Cinquefoil, and seven Mosses. Fascinating as is the meadow, it is only one of scores of places equally interesting and beautiful. Of two paths from the meadow, one leading through the woods presents a greater variety than the other, following a wagon-way which crosses between two township roads. We enter the path where it runs close beside a little brook, here curving around some Beeches, the only ones to be found in this part of the mountain. A short distance beyond, four majestic White Oaks, growing equidistant about twenty feet, dwarf everything near them. Through almost the entire length of the path the stream is in sight, sometimes screened by the waving fronds of superb *Osmundas*, at other times hidden by the Ironwoods, whose delicate foliage in certain

atmospheric conditions appears like a green mist. Aspidiums and Maiden-hair Ferns border our path, the sunshine wavers across the Spice-bushes and against the trunks of some fine Maples, which give their name to this "Sugar-camp Path."

Half-hidden by Ferns, and Spikenard with its graceful racemes of crimson-purple berries, we see the old troughs at the base of the trees. One moment we are apparently in the depth of a forest, the next we have passed between Alders into a sunny lane, between the upper Clover-field and the "Spring-house Meadow." This meadow is a complete contrast to the one we have just left, for here the grass shows only a few pale Violets and *Spiranthes* instead of the crowded life below; but long after the lower field has faded into monotonous gray this little sheltered spot remains green, and is a most beautiful setting for the home-acre.

Mira Lloyd Dock.

A Campaign against the Tent Caterpillars.

DURING the last few years the road-sides in the vicinity of Boston, as also in other portions of the state, have been infested in the month of May by hordes of Tent Caterpillars. In some districts rural beauty has been seriously impaired by them, and the ravages of these insects have become an insupportable nuisance. Making their appearance at the season when the leaves of the Apple and Cherry are just unfolding and when the fresh spring foliage is everywhere at its best, the destruction caused by them is painful and depressing to behold. Entire trees and shrubs are completely stripped of their leaves, while myriads of their unsightly nests are left to dangle from the bare branches. To the lover of natural beauty words can hardly depict the appearance which an infected region offers; nor is the sight less revolting which is presented by the remains of the worms crushed under the foot of man and beast, as they crawl in thousands even to the upper rooms of dwelling-houses in search of proper shelter for weaving their cocoons.

In the course of the past year the Newton Horticultural Society had its attention called to this subject by several members, and steps were taken to arrest, or, at least, to mitigate, the evil. A circular was issued giving an excellent plate, illustrating the various stages of the development of the insect, and offering various prizes for its destruction as well as the following information: "The moth lays its eggs on the small twigs of various trees and shrubs, mostly of the Apple and Wild Cherry, in the form of a belt, which encircles the twig. This belt of eggs is covered by the moth with a brown mucilaginous substance, which serves to fasten it firmly in its position, while it protects it from the weather and from other injuries. The belt should be removed from the tree by cutting or breaking the twig upon which it rests, and preserved in a cool place. It will be necessary to present these for examination in competition for the prizes to one or more of the committee whose names are signed to the circular."

In this good work the Horticultural Society had the co-operation of the Newton Centre Improvement Association. As a result, \$75.00 were distributed in prizes and gratuities among the competitors, the first prize of \$15.00 being given to a young lad who presented over 14,000 belts. The gratuities bestowed were for the purpose of inciting future interest in this direction, and were from the private purse of a generous citizen.

In order that the work may be carried forward systematically next year, a circular has been prepared and sent to the citizens of Newton, in which it is stated that probably 25,000,000 eggs of the tent caterpillar were destroyed last year, and that, in order to stimulate the efforts of the boys and girls of Newton, it is proposed to offer \$1.00 for every lot of 1,000 belts. As this will require funds, contributions are invited. The circular also invites the attention of landholders to the fact that worthless trees and shrubs growing on their premises, especially Apples and Wild Cherries, should be cut down, as they are favorite breeding-places for numerous pests. In addition to this circular an advertisement was placed in the local papers, announcing that the Newton Horticultural Society would pay a bounty for every lot of 1,000 belts of eggs of tent caterpillars received before the first of April. It may be added that it is eminently wise to prepare for the work at an early date, so that collections can be made during the winter and spring months.

It is to be hoped that the praiseworthy example of the Newton Horticultural Society may be followed by the adoption of similar or better plans, if possible, by all towns and villages for the extermination of this pest. It would seem, from experience, that the most feasible method of destruction is by collecting and burning the belts of eggs before the period of hatching, which varies with the season, being in this latitude

from the middle to the last of April. After the nests are formed, the work becomes one of much greater magnitude and much less satisfactory.

Daniel Denison Slade.

New or Little-known Plants.

Galax *aphylla*.

THIS is a handsome and interesting plant. It is interesting as the representative of a monotypic genus of a small although very widely scattered family (*Diapensiaceæ*), which is represented in the flora of eastern North America by the beautiful Pixie-flower, *Pixydanthera*, of the sandy Pine-barrens of southern New Jersey and North Carolina, by another monotypic genus, by *Shortia*, of which a figure and description will be found in these columns (vol. i., p. 509), whose only relative is in Japan, and by *Diapensia*, with a single northern species which extends to Greenland and then eastward to Japan.

Galax (see page 605) is a glabrous herb with red creeping and matted root-stalks, which send up round-cordate thickly crenate-dentate veiny thin leaves, which are persistent through the winter, an inch and a half to two inches across and long-stalked. The single flower-scape is slender, sometimes two feet tall, almost destitute of bracts, and terminated by a virgate spicate raceme of many small white flowers. These are composed of a five-parted minutely two-bracteolate calyx, a corolla composed of five entire oblong petals, which are distinct except where their bases are adnate with the base of the monadelphous stamen-tube, which is ten-lobed above, the lobes alternate with the petals, being short and bearing sessile introrse anthers, while those opposite the petals, which are really staminodia, are larger, linear-spathulate and petal-like. The style is very short, and is crowned by a slightly three-lobed stigma. The fruit is an ovate capsule filled with angular seeds.

Galax is a common plant in the region of the southern Alleghany Mountains, from Virginia to Georgia. At elevations of three or four thousand feet it often covers the ground under Hemlock-trees and other evergreens with great carpets of its beautiful shining leaves, and when the plants are in flower the appearance of this undergrowth is specially beautiful and attractive.

Galax has a bad name with cultivators, and it is rarely seen in good condition beyond the borders of its native home. It was introduced, however, into English gardens as early as 1756; and that it can be cultivated if proper attention is paid to its wants is proved by the great mass of plants in perfect health and beauty which for at least fifty years have been growing and extending in the Knap Hill Nursery in England, where four generations of Waterers have been cultivating and improving American plants.

Of late years great quantities of handsome circular lustrous leaves of a dark vinous color have appeared every winter in the shops of florists in this and other northern cities, and numerous inquiries are addressed to us every year as to the name of the plant which produces these leaves and the source of the supply. They are leaves of *Galax* gathered among the mountains of Virginia and Carolina and sent north for winter decoration, for which purpose their size, shape and color well fit them.

Foreign Correspondence.

Centrosemas.

IHAVE received inquiries from several American correspondents, and also from friends in England, with respect to the merits of the *Centrosemas*, and particularly of *C. grandiflora*, as garden-plants. We have two species in cultivation at Kew—namely, *C. Plumieri*, an old introduction, generally known, I believe, as a *Clitorea*, and *C.*

Virginianum, which was introduced from the West Indies last year as "a new and beautiful species of Clitoria."

Of the other twenty-four species of *Centrosema* known to botanists, none, so far as I can ascertain, have ever been

The genus is almost entirely American, chiefly Brazilian. It is a near ally of *Clitoria*, of which genus *C. ternata*, a stove-climber, with large pea-shaped deep blue flowers, is a well-known garden-plant. All the species are more or

Fig. 103.—*Galax aphylla*.—See page 604.

cultivated here as garden-plants. Judged by dried specimens in the herbarium, by pictures and the descriptions of botanists and collectors, a considerable proportion of these plants are deserving of the attention of gardeners.

less climbers, some of them twining like a Scarlet-runner, others being of less rambling habit. The leaves are generally trifoliate, the leaflets *Phaseolus*-like, except in one or two species, in which two of the leaflets are entirely sup-

pressed. The flowers are papilionaceous, and are remarkable for the large size of the vexillum, or standard, which in some of the species measures fully two inches across. They vary in color from white to rose, violet and blue, and generally they are prettily lined or shaded with other colors. They appear to fruit as freely as the Kidney Bean, the pods generally being long, narrow and four-angled. *C. Virginianum* has produced a very large crop of good seeds with us this year. The pods of some of the species are eaten as we eat beans. The two species under cultivation here are stove-climbers; at any rate, we find they thrive perfectly in a stove. Possibly, however, *C. Virginianum*, which is, I perceive, a native of the southern United States, may be successfully grown in an ordinary greenhouse temperature, or even out-of-doors in summer. It may be as hardy as the Sweet Pea, although the species are most abundant in tropical regions.

The following species appear to be worth introducing for trial in the garden:

Centrosema platycarpum. This has exceptionally large broad pods and large purple flowers. Kalbreyer, who collected it in Ocana, describes it as a "papilionaceous twining half shrub, eight to ten feet high, with large single deep purple flowers and large trifoliolate leaves." It is also found in Brazil and British Guiana.

Centrosema coriaceum has small Willow-like leaflets, and forms a suffruticose procumbent shrub with large blue flowers. It is Brazilian.

Centrosema vexillatum has ovate leaflets three inches long, and beautiful flowers two inches across. Schomburgk, who collected it in Guiana, called it a herbaceous twiner with large flowers, colored white, with blue streaks, and a purple disk.

Centrosema Brasilianum is another stout climbing shrub with large flowers of varying shades from lilac to blue and violet, some having stripes of yellow through the standard. It is, or was, common in Trinidad.

Centrosema macrocarpum has large edible pods and white flowers, striped with blue. It is a native of Guiana, etc.

Centrosema pubescens is another large handsome-flowered species which Linden found in New Granada, and Kalbreyer in Ocana at an elevation of 4,000 feet.

Centrosema Plumieri is a coarse climber, with large kidney bean-like leaves borne on stout, twining stems. The peduncles are axillary, and each one bears five or more purple and white flowers, one and a half inches across. It was introduced from the West Indies by Dean Herbert, and flowered in his hot-house in October, in 1837. Lindley figured it in his *Botanical Register* as *Clitoria Plumieri*. It is common in Brazil.

Centrosema Virginianum was in cultivation in England over sixty years ago, but it does not appear to have become popular. It was introduced to Kew last year, where it flowered most profusely in the tropical Water-lily house, its thin twining stems running along the roof for about two feet, and flowering from every leaf-axil. The peduncles are short, and they bear two or three flowers each, the flowers being one and a half inches across, pale lilac lined with purple. The pods are very narrow, and about six inches in length. Treated as a stove-annual, and grown in pots, with the stems trained about a light trellis, this plant would be decidedly attractive. According to Lindley, who figured it as *Clitoria Virginiana*, it grows on hedges in Virginia and Carolina, also in Jamaica and San Domingo. It varies in the size of its leaves, and some of the flowers are white, others lilac.

Centrosema grandiflorum. This is described by Bentham in *Martius' Flora Brasiliensis* as a climbing shrub, with thin glabrous stems and trifoliolate leaves, the leaflets from two to four inches long by one to two inches wide, smooth above, velutinous below. Peduncles axillary, short, bearing from three to seven flowers, in which the vexillum is one and a half inches in diameter, and silky. The pod is six inches long and glabrous. The plant is wild in Central Brazil and in Caldas in Minas Geraes.

This species, or what is supposed to be this, has been described by one who has it in cultivation as "a perfectly hardy climbing plant, of rare and exquisite beauty, which flowers early in June from seeds sown in April, and bears in the greatest profusion inverted pea-shaped flowers from one and a half to two and a half inches in diameter, varying in color from a rosy violet to a reddish purple, with a broad-feathered white marking through the centre. The large buds and the back of the flowers are pure white. Sometimes six or eight flowers are produced in a single cluster. It is well adapted for every garden, especially as a climber, running six to eight feet in a season. Even in the poorest soil it will bloom freely until cut down by frost." This description might easily be mistaken for that of one of Mr. Eckford's latest Sweet Peas!

NEW CHINESE LILIES.—The genus *Lilium* promises to be exceptionally well represented in China, the number of species now known from that country being twenty-four.* Monsieur Franchet, of the Paris Herbarium, has recently published in the *Journal de Botanique* a classified list of all the species of *Lilium* now known in China and Thibet, prepared from the collections made in those countries by Monsieur Delavay and others, including Dr. Henry. Mr. Baker has made a brief abstract of this paper for the *Gardeners' Chronicle*, adding a few words about each of the new species. Of these there are twelve, and some of them are evidently very beautiful. Thus *L. formosum* has white broadly campanulate flowers six to seven inches long; *L. Delavayi* has flowers like those of *L. candidum* in form, and colored wine-red, with brown spots; *L. ochraceum* has flowers of the Martagon type, colored yellow, unspotted, with oblong segments; *L. myriophyllum* has very numerous leaves and erect, white, large, cup-like flowers; and so on. It is to be hoped that the French collectors have sent home seeds or bulbs of these plants in addition to the dried specimens. The distinct, beautiful, hardy *L. Henryi*, which, by the way, is omitted from Mr. Baker's list, was introduced in this way from China to Kew by Dr. Henry. Collectors of plants for herbaria should always obtain as far as they can seeds or living material of some kind of all interesting plants for cultivation. If these new *Liliums* are as hardy and free-growing as those species which are already established favorites in the garden, they will be a very valuable addition to cultivated plants. We have nothing much better than *L. speciosum*, *L. longiflorum*, *L. tigrinum* and *L. giganteum*, and these are of Chinese origin. Mr. Baker says: "The collections that have been made lately in western China and Thibet have shown that these regions are exceedingly rich in new types, belonging to many of our favorite garden genera." Here is a useful hint for collectors.

London.

W. Watson.

Cultural Department.

Irises and their Cultivation.—I.

THE publication of Mr. James Baker's *Manual of the Iridæ*, as announced lately in GARDEN AND FOREST, is sure to be welcomed by every owner of a garden, where hardy plants are valued and studied. There is no other important family of plants about which reliable information has been more difficult to obtain by persons who do not have access to botanic gardens. The publication of this book from such an authoritative source is sure to give a new impulse, not only to the collection and cultivation of the Irises, but, it is also to be hoped, of the less known species of *Gladiolus*, which seem to have mostly disappeared from cultivation. It will be a comfort to have a manual, to which one can turn with confidence in the effort to determine the true species, and discover synonyms, not always a simple matter to one with little botanical knowledge. If plants are to be labeled, it is a matter of the first importance that they shall be labeled correctly, and for this we must depend on the acumen of the scientific botanist. In a horticultural way, of course, we are compelled to make certain compromises with scientific knowledge when the distinctions, botanically, seem closely drawn. *Moræas*, for instance,

* Twenty-five with *Lilium Henryi*.

Fig. 104.—Grove of Cedars on Mount Lebanon.—See page 602.

which are still relegated to a separate genus, will probably, in a garden, be always counted as Irises. An ordinary observer would not see any difference, and it would embarrass the average grower to attempt to explain their distinctions. Counting the *Moræas*, we have, it seems, something over two hundred distinct species of Irises recognized at present, to which, probably, we shall constantly receive accessions. These, with the numerous varieties and hybrids, offer, certainly, a most extended and interesting field to the gardener and student.

As was said editorially a few weeks since, the Irises have ever been the favorite plants of the hardy garden. Though seldom grown in large variety in the average garden, few gardens are without one or more kinds. Next to the double yellow *Narcissus*, there is probably no plant more widely disseminated in gardens through the country than the common *Fleur de Lis*. In the older sections of our country, at least, *Narcissus telamonius plenus*, *Iris Germanica* and *Lilium candidum* are a trio, all, or one or more of which, may be found in most old gardens. Besides the *Iris* mentioned, there are few varieties to be found in country gardens in this section. At least, a flower-loving friend, with a fancy for Irises, has searched this country-side very thoroughly to add to his collection, and has discovered less than a dozen, and these mostly hybrids, or the so-called German Irises. As some other sections of the country may possibly have the same dearth of these plants, it has occurred to me that a few notes on the family may be helpful and suggestive to others, for among the species and varieties are many very interesting plants, second to no others in beauty and garden value, and plants, too, for the greenhouse, the cold-house and the hardy garden.

The species embrace a great range, and it is impossible to give general directions for their culture, for, while some species are very difficult subjects to flower, many kinds are very easily grown, increase very rapidly, and are thoroughly reliable and satisfactory garden-plants. The bulbous kinds mostly are better for an occasional replanting, though among these there are a few which seemingly take a very short rest, and should not be kept out of the ground many weeks. The other sections resent removal, and are somewhat slow to establish thoroughly. They mostly have good, strong, long roots, and appreciate a good deep soil, not too heavy. It is usually a gain to plant these in the early fall to give them a chance for the following season. While some kinds, such as our common *I. versicolor*, are often found growing as aquatics in a foot or more of water, they do equally well in a dry border. While a fair amount of moisture, not stagnant, is appreciated by most of these Irises, care should be especially taken to plant those whose rhizomes creep at the surface, so that water can freely flow from them. Apparently the only *Iris* whose flowers are susceptible to increase in size by cultivation is *I. lævigata*, forms of which, known as *I. Kämpferi*, the Japanese have supplied to us. These, while growing vigorously in a dry border, respond to liberal treatment in the way of water and stimulants by giving increased size of flowers. Some of the rhizomatous Irises are said to do well as pot-plants if the roots are crowded, but the few tried by me have as yet failed to flower. *I. Tectorum* (the Roof *Iris* of the Japanese), for instance, the leaves of which are very graceful, has failed to flower after two years of closely potted life.

Elizabeth, N. J.

J. N. G.

Carnations for Market.

THE Carnation in America has become a distinct type. In a literal sense it is a product of the soil. The home-raisers have the field, and the market, too. No foreign importations approach the standard now attained here. A variety to hold its own must be a true Perpetual, of free, low-growing habit, with grassy foliage, allowing the free access of light and air. It must have good stiff flowering stems, with productiveness and good shipping qualities are essential. Owing to the demands of the market, selection during recent years has been in the direction of longer stems. Where a stem produces a number of buds the flowers are small by comparison, unless disbudding is practiced, and growers seldom have the time or inclination to do this. Even with the best varieties, enough short-stemmed buds are produced to meet all the demands of the market for button-hole and bouquet work, and more than this is a dead loss. Another important qualification of a new variety should be a tendency to produce after the first crop an unusually large proportion of single buds. This has always been a good quality of *Grace Wilder*, and, perhaps, explains why it has remained so long in the front rank among pink Carnations. The same is true of Mrs. Fisher among white varie-

ties, since in this respect it is superior to *Lizzie McGowan*. A good crimson like *Anna Webb* or *Ferdinand Mangold*, with these qualifications, would be a treasure indeed.

Carnation-growers are springing up everywhere, and when it is considered that the outlay for establishing a business in this direction is comparatively light, there is some fear among the older growers that the market will be overstocked. One certain result will be to increase the average quality of the flowers. For first-class blooms there always has been a good market, and the indications are there will continue to be.

To the question, Which is the best white variety for market? growers hereabout unanimously answer Mrs. Fisher. It is a true Perpetual, a heavy and continuous cropper and an excellent shipper. It bears a good-sized, round, full double and sweet-scented flower. During a recent visit to Mr. Nickolson's, of Framingham, I saw part of a lot of 500 plants struck last January, and planted outdoors May 20th, which yielded between the 15th of July and the 20th of September an average of 1,500 flowers per week. These same plants were at the time of my visit (December 5th) blooming in very good form, and there was no apparent difference between them and the remainder of the lot, which were struck later and not allowed to bloom, except that the plants were slightly taller. The argument that certain varieties have a local adaptation seems to hold good in the case of this variety, which is scarcely grown outside the limits of the Boston trade, and has been contemptuously dubbed by the New York and Philadelphia growers the Boston White. Mr. James Tulis, grower for Mr. Homer Rogers, of South Sudbury, has four large houses devoted to it exclusively. The practice adopted here of growing each variety separately has much to commend it. The particular needs of each can be better studied and attended to.

Lizzie McGowan, the popular New York and Philadelphia white, is finding some favor. Its constitution is good, its habit perfect; the stems are stiff, with fine grassy foliage, which admits light and air freely, an essential quality in a winter-bloomer. Its principal defects are lack of substance, and, consequently, poor shipping qualities, and, moreover, it is only slightly fragrant. *Silver Spray* stands well in comparison with other market varieties; it is a fair shipper and a good keeper. *Puritan*, a new white, sent out by Woods Brothers last year, is the most promising white among recent introductions. The flowers are very large, of the purest white, beautifully fringed, and have a delicious clove fragrance. It is a fine healthy grower, but, so far as tested, is not a heavy cropper. *Tailby's Grace Wilder* is the ideal pink-variety, and singularly free from any tinge of purple at any stage. It is erect, low-growing, with fine grassy foliage, producing after the first crop an enormous percentage of single buds, rendering it distinctly valuable for long stems. The flowers are finely formed, though not large, beautifully fringed and very fragrant, keeping well when cut. It is, moreover, a true Perpetual, and in this respect is superior to a large number of new varieties of this shade, which, strange to say, more than any other revert to the old border type when raised from seed. *Ada Byron*, one of Mr. Fisher's new rose-colored varieties, is very promising. It is vigorous in constitution, with good blooming qualities, although rather late. The flowers are perfectly globular, on good stout stems, neatly fringed and fragrant. *Nickolson*, another of Fisher's, promises well, though not quite satisfactory. It carries a good round flower on stout stems, but is not, so far, a heavy cropper. The color is a lovely red-rose. *Daybreak*, the new and popular flesh-pink, fully bears out the reputation it has everywhere earned. It is a good healthy grower, though not very prolific. The flowers are very large and finely formed and very attractive.

There is a variety of opinions as to which is the best scarlet. Some grow *Portia*, a really good bright scarlet, though lacking size; others like *Florence*, while some prefer *Hector*. The latter variety is hard to beat where it succeeds. The flowers are of the largest size, of the clearest and brightest scarlet. *Florence*, a more reliable variety, said to be the seed parent of *Hector*, is a good clean grower and a splendid cropper. It has the defect, however, of weak stems, and produces an undue proportion of short buds. Mr. James Tulis grows three houses of it, which are carrying an immense crop of bloom. E. G. Hill, a promising new scarlet, is on trial, rather a coarse grower.

As to the best crimson now on the market, honors are divided between *Anna Webb* and *Ferdinand Mangold*. Both are strongly clove-scented and very similar in every way; the latter is said to be a seedling from *Anna Webb* and perhaps possesses a trifle more vigor. As far as I have seen them when growing together I have failed to see any difference; Mr. Tulis, however, has discarded *Anna Webb*. He had at the time of my visit a magnificent houseful of *Ferdinand Mangold*. The

air was filled with the perfume of more than three thousand blooms of large size and perfect form. It is not, however, a very profitable variety to grow, owing to the large number of side buds. In a white variety this is not so serious a fault, as many short stems are used in bouquet and other work.

Striped, or flaked, Carnations are not popular, owing to the prevailing fashion of arranging colors separately; for this purpose, distinct and telling self-colors are preferable, but when a mixed cluster is desired a few bizzarres contrast beautifully with the others. Mary Fisher is a lovely violet striped on yellow ground. Paxton is one of the best crimson striped on white ground.

Raising seedling Carnations is a fascinating pastime, if not very profitable. As with Chrysanthemums, there is no certainty that the results desired by making a certain cross will be reached. The general opinion is that the tree, or perpetual blooming, varieties have been evolved from the border kinds. But several years ago, when raising border kinds only from seed, I found among them very many true Perpetuals. Raisers here say that seedling Perpetuals often run back to the border kinds, and it is only by very careful selection the ever-blooming standard is maintained. And afterward, in order to perpetuate the variety true to character, it is necessary to select cuttings only from the flowering stems, a fact not duly considered by introducers of new varieties.

Wellesley, Mass

T. D. H.

Notes from the Harvard Botanic Gardens.

PLEROMA MACRANTHA.—One occasionally meets with this excellent plant in good condition throughout the country, but it is in general neglected. It is a free-growing shrub, branching abundantly, and may be grown to neat bush specimens or trained on a light-colored wall with equal effect. The opposite, ovate leaves are from three to four inches long, rich green on the upper surface, much paler underneath, and densely pubescent, as are the young branches. The flowers are borne singly on the upper portion of the shoots, and they are from four to five inches in diameter and of a rich blue-purple shade. The color, so rich and uncommon among our greenhouse-flowers, gives these flowers great value; and were it not for their brief duration of but two or three days, this plant would rank among the most useful of those cultivated under glass. The flowers, however, are produced so plentifully and in such quick succession in autumn and winter that their fugaciousness can be partly overlooked. Young plants only a few inches in height bloom quite as profusely in proportion to their size as larger ones, and, therefore, several of them are desirable in decorative collections. A few of them dotted here and there in a group of foliage or other flowering plants add a distinct richness of appearance, and since they can be grown with little trouble, it is astonishing that the plant is not more generally used. It was introduced in 1864 from Brazil, and with us thrives best in an intermediate temperature, with all the air and light possible in summer, without exposure to strong sunshine. The growth is made in the warm season, and at that time the plant needs plenty of water; but the supply must be gradually shortened as the flowers appear, and a very small quantity will suffice in winter. Plants intended for bush specimens may be sparingly pruned into shape at the termination of the flowering season, and repotted in spring. Cuttings of the young wood rooted in early spring will make neat flowering plants the following autumn. *Lasiandra* is a synonym of *Pleroma*, and often used in connection with this species.

URCEOLINA PENDULA.—This rare and lovely stove bulbous plant is now in bloom. The bulbs, as we find them in gardens, are roundish, and from two to three inches in diameter. Each bulb develops two, sometimes three, dark green oblong leaves about twelve inches in length. The drooping flowers are borne in large panicles at the apex of an erect scape from twelve to eighteen inches high, the filiform peduncles measuring an inch in length. They are urn-shaped, and the conspicuous portion is about two inches long by half an inch diameter, a rich golden-yellow for two-thirds of its length, the divisions being deep green, margined with white, at the spreading extremity. The leaves disappear when they have completed their work, thus leaving the plant wholly destitute of foliage, when the flowers develop a few weeks later. The bulbs should be turned out of the pots before they commence to grow in spring, and, after carefully removing the exhausted earth from about them, replaced collectively in large pots, or singly in small ones, keeping the summit of each on a level with the surface of the soil. They must now be placed in the stove and kept dry until growth begins, when water may be given

freely until the leaves have attained their full size and show signs of changing color. The supply of water should be gradually diminished as the leaves turn from green to yellow, and little or none will be necessary afterward. After flowering, the plants may be placed on a dry shelf in an intermediate temperature, and kept there until the following spring. *U. pendula* is propagated from seeds and offsets. Some English nurserymen, Messrs. W. Clibran & Son, of Altrincham, have recently been successful in obtaining a hybrid between this plant and *Eucharis grandiflora*. The new plant is figured in the *Gardeners' Chronicle* of August 20th last under the name of *Urceocharis Clibrani*, where it was described as interesting and beautiful, with flowers in character curiously intermediate between those of the two parents.

PLUMBAGO ROSEA has been known to cultivators since 1777. It bears dark red flowers, but is not so decorative as its variety *Coccinea*, obtained by the Messrs. Veitch, from the Nilgiri Hills in 1863. The latter plant, now in full bloom at this place, was very popular for winter decoration some years ago, but it seems to be greatly neglected now. It is a compact, evergreen shrub, from three to four feet high, the branches clad with alternate, oblong-ovate, bright green leaves, measuring from six to eight inches in length. The flowers are almost sessile, and borne in graceful terminal panicles from twelve to twenty-four inches long. The slender tube of the flower, emerging from a short calyx, is nearly an inch and a half long, and the spreading limb of five or six obovate parts, rather more than an inch across. The color is much brighter than that of the species, and the flowers themselves are produced in far greater profusion. The plant is constantly in bloom during the winter months, and it requires a stove or intermediate temperature. It is easily propagated by cuttings. Old plants should be invariably potted in spring, and a week or so before they should be pruned to within two or three joints of the old wood. They like a humid atmosphere when growing freely, but a trifle less heat and moisture will be beneficial later. A position close to the glass will always help secure their best development, and a little shading is necessary in summer, although the flowers take on a deeper and stronger color under full light and sunshine in winter.

M. Barker.

The Forest.

The White Pine for Timber.

FEW questions in practical forestry have greater interest than those which relate to the best methods of growing the White Pine. Mr. Edmund Hersey has lately prepared an instructive paper on the general subject, which has been issued as a bulletin by the Bussey Institute. We publish this paper below, together with some notes which Mr. B. E. Fernow, Chief of the Division of Forestry at Washington, has prepared at our suggestion. We should be glad if other correspondents would give their views, since a full discussion of every phase of the subject is desirable.

As a timber-tree the White Pine possesses more good qualities than any other tree that is a native of Massachusetts. It is easy to grow it from the seed or transplant it when young; it will grow on a light sandy soil or on a peat-meadow; (1) on an ordinary soil the growth is quite rapid, making in thirty-five years from the seed a tree large enough to be sawed with profit into box-boards or coarse lumber; it makes lumber that can be used to advantage for a great variety of purposes.

When a Pine-forest is to be grown from the seed, an effort should be made to secure seed that is new and taken from the cone but a few days before the time it is wanted for planting. (2)

The cones containing the seeds begin to grow in June, and when of the size of the end of one's finger they stop growing until the following year, when, during the summer, they grow to full size, and perfect their seeds early in September; the first frost severe enough to kill Squash-vines opens the cones and the seeds drop out; (3) they are about the size of a Parsnip-seed, are very light in weight, and, having a little wing on them, they float along through the air in a slightly downward direction, reaching the ground sometimes twenty rods from the parent tree, but more frequently not more than from one to five rods. Soon after reaching the earth the little wing separates from the seed, and if the seed is to germinate it becomes partially or wholly covered with earth by a heavy rain, or by the pressure of the foot of a passing animal, or the falling

leaves may furnish sufficient protection to preserve its vitality. When nature is permitted to carry out her own plan of propagating the White Pine her work is more irregular than when assisted by man. Should the seeds leave the cones when there is but little force to the wind, they will drop very near each other at no great distance from the parent tree, and the result will be that a hundred small trees will grow on a space not large enough for more than one large one; but if the seeds leave the cones when the wind is high they will be carried great distances and spread over a wide territory. When man, without too much labor, can assist nature in the more even distribution of the seed it is desirable he should do so, but when he cannot, he may be able to prevent crowding by removing some of the small trees where they cover the ground too thickly, and setting them out in another place where they cannot interfere with each other.

When the seed is to be planted by man, the cones should be gathered just before the first frost in the autumn and placed small end up in the grass away from all enemies. After the first heavy frost, gather up the cones and shell out the seed by turning them small end downward over a vessel and giving them a rap with a stick, when the seeds will drop out. As soon as the seed is shelled it should be planted; it is a mistake to dry Pine-seed several months before planting.

The method of planting must depend on the condition of the soil; if it is a barren plain, shallow furrows may be plowed from east to west five feet apart, turning the furrows to the south, to afford a partial shade to the young plants. The seed should be planted on the south side of the open furrow, dropping two seeds near each other, then leaving a space of four or five feet, and covering the seeds with earth enough to keep them moist, say not far from one-half an inch in depth. (4) On rocky land, or where the soil is hard, dig out with a sharp spade a small sod where the seeds are to be planted, leaving the sod near the hole on the south side for shade, and planting the seed the same as in furrows. In a favorable season enough seed will germinate to cover the land; but if the season be unfavorable, a portion of the land will have to be reseeded the following year. Where the land is shaded by trees, germination will be more certain; but in such places when the seedling Pines are two years old they should be let out into the sunshine by removing the trees that shade them.

In localities where seedling Pines that grow naturally are numerous, it is not expensive to cover land with Pines by transplanting the young trees; to do this to the best advantage trees should be selected that are not over six inches in height, and in removing them a small ball of earth should be removed with each tree, care being taken not to expose the roots to the light or the air, and it is always best to do the work on cloudy days. The trees should be set five or six feet apart, and as they grow a sufficient number should be cut out to prevent crowding. When large enough for box-boards or coarse lumber, not more than four or five trees should be left on each rod of land.

On an average soil, thirty-five years is sufficient to produce White Pine timber of a profitable size to cut for coarse lumber, and, as a rule, on our New England soil; it is more profitable to cut the trees at this age than it is to let them stand long enough to produce trees large enough for clear lumber. It is a mistake to suppose that trees large enough and good enough for clear lumber can be grown on any soil; it is only on soils best adapted to the growth of the White Pine that it is wise to let the trees stand after they are more than twenty inches in diameter. On ordinary, and even on very barren, soils, the young trees grow quite rapidly, and unless the soil is very unfavorable, they will make a satisfactory growth until the largest trees are ten or twelve inches in diameter; beyond this size, if the land be well covered with trees, a very large portion of them will show signs of decay, and only a few growing in the most favored places will continue to grow rapidly; thus the decay on the lot will be nearly equal to the growth.

While it requires but from twenty-five to thirty-five years to grow the White Pine large enough for box-boards, it requires from sixty to seventy years to grow it large enough for clear lumber. When we consider the fact that there is always a ready sale, at remunerative prices, for coarse lumber, and also the uncertainty of getting first quality of lumber by thirty years of additional growth, it would seem unwise to encourage owners of Pine-timber forests to let the trees stand after they are large enough for coarse lumber, except on land strong enough to keep up a rapid growth until the trees are three feet or more in diameter. (5)

Four White Pine-trees set thirty-one years ago now measure, three feet from the ground, as follows: one sixty inches in circumference, one sixty-five inches and two sixty-six inches; the

sixty-five-inch tree grows in a wet soil, the remaining three are in a gravelly loam not rich enough to produce more than 800 pounds of hay to the acre. These trees when transplanted were not over six inches in height, and they have grown with other trees set at the same time so near each other that they now completely shade the land. Two trees set on a poor gravelly knoll twenty-five years ago now measure thirty-three and thirty-nine inches in circumference; these trees were about twelve inches in height when set; they have grown on open land.

There have been many opinions advanced in regard to thinning and trimming White Pine forests, and these divergent views have to some extent been caused by a difference of opinion as to how long the trees should be permitted to grow. If a Pine-forest is to be cut when large enough for coarse lumber, it should be treated differently from one that it is to stand long enough to make clear lumber; but little need be done with the former except to cut out the dead and dying trees, while the latter should be carefully looked after from the time the trees are eight feet high until the limbs on the trunk are all off to the height of twenty or more feet. As early in the growth of the forest as possible, the trees that are to remain for lumber should be selected, and the lower limbs on the trunk cut off as fast as it is considered safe to do so and not injure the vigor of the tree; this work should be done in June. After having chosen the trees that are to make the future forest, all the trees between them should be kept back and destroyed as fast as they appear to crowd the selected trees; but it is well to let the trees between stand quite near to the selected ones until they are twenty feet high if they do not overshadow them. By so doing the trees will grow higher and the trunks will have fewer limbs, thus securing clear lumber; in fact, a good White Pine timber-tree rarely ever grows in an exposed position; it must grow where it is surrounded by other trees, or it will not make a long, straight and clear timber-log; he who is to trim a timber-lot must ever keep this fact in mind, and do his work in such a manner as will best assist nature in her efforts to produce trees of the best type for man's use. It is not wise to attempt to grow more than 160 or 170 timber-trees to the acre, but by the selection of this number when the forest is young, they may be given ample room to develop, and there will be left room between them to grow a limited number of trees large enough for box-boards.

Edmund Hersey.

The article on White Pine, submitted for my examination, contains many good ideas and correct statements, but is not, in my opinion, correct in all respects. It contains many theories that are novel and which need to be proven, and some theoretically correct ideas which do not admit of practical application. For convenience I have indicated the passages with digits upon which I have commented.

(1) While certainly the White Pine will grow, and even thrive, on a wide range of soils, it would be misleading to name a badly drained soil, like peat-meadows, as a locality for it when speaking of its cultivation, and it should have been stated that the best site for it is a fresh to moist, well-drained sand-soil, although even a drier soil yields good results if only deep or permeable enough.

(2) This method of securing seed is neither necessary, nor in most cases practicable. It has, on the contrary, been well established for most coniferous seed, that a certain time of after-ripening increases the per cent. of germination. Most Pine-seeds are best kept over winter and sown in spring, as nature does. The White Pine is a curious exception, shedding its cones in the fall, and thereby indicating, perhaps, that fall-sowing is preferable for it.

(3) The theory that frost opens the cones is new. It is the drying by evaporation from the scales, and the consequent contraction of the outer-cell elements at their base, which makes the scales open; the same process which makes leaves and cones drop eventually. As the cones open near the beginning of October, he who waits for frost may lose his harvest. He had better cut the cones the first weeks of September, spread them on a dry place, a gently sloping roof, for instance, where the sun will open them, and the seeds can be readily knocked out and swept together, or else the drying may be done in warm rooms. The resin on the cones will prevent many seeds from fall-

ing out readily. One bushel of cones will yield less than half a pound of pure seed. In Germany the cones of Scotch Pine are sometimes spread at once over seed-places, and after sunny days turned with brooms to let the seed drop. Rainy days close the cones again.

(4) I would suggest that a more liberal use of seed would in the end be more economical, for the vicissitudes to which the seed is exposed under the unattended conditions of the forest-growth—different from nursery conditions—will necessarily prevent many from germinating; hence an abundant supply, say at the rate of three to four pounds per acre, promises surer success. I would caution those who propose to sow White Pine under the shade of older trees to make sure that the shade is not too dense and that it is soon enough removed. The absence of reproduction of White Pine in our forests, which has led lumbermen to deny that it can be reproduced at all, is probably largely due to the unfavorable light conditions which the seedlings find in the culled forest, where the shade kills them eventually.

(5) While the argument that it is more profitable to grow box-board pine than clear lumber pine may be correct, the writer owes us the proof or at least the basis for his assertion. I admit that profitableness of forest-culture, especially a comparison of the profitableness of two different methods of forest-management in the United States, is a matter almost impossible to discuss on account of the many uncertain and changeable quantities in the calculation. But it would have been possible to furnish some of the facts that need to be known even to estimate possibilities, namely, the quantity of material produced, and its quality at different ages per acre, and present prices for such amounts and qualities, when, together with an interest calculation on expenditures, the greater or lesser profitableness might be estimated. I have no reliable definite data as to yield from which to calculate the comparative profitableness of white pine under the given conditions. Possibilities, however, may be figured as follows: An acre of White Pine on poor soil may yield at thirty-five years 2,000 feet of box-boards at ten dollars a thousand, and ten cords of fire-wood at fifty cents a cord, or altogether twenty-five dollars. At eighty-five years we might expect from the same acre besides some ten cords of fire-wood taken in thinnings, if well managed, at the very least 8,000 feet B. M. of varying qualities, averaging at least sixteen dollars a thousand, and in addition forty cords of fire-wood at probably more than fifty cents, because containing more split-wood, the wood crop altogether amounting to at least \$148.00 per acre. If we had bought the acre at thirty-five years after planting for the twenty-five dollars which its crop represented, this would represent compound interest at more than ten per cent. It is to be expected that prices for white pine will have considerably appreciated in fifty years, and the yield by proper management could certainly be increased by fifty per cent., which would bring it to what is expected of Spruce in Germany on third-class soil. If Mr. Hersey has reliable figures to show otherwise, I should be glad to see them.

Washington, D. C.

B. E. Fernow.

Correspondence.

The Texas Barberry.

To the Editor of GARDEN AND FOREST:

Sir,—*Berberis trifoliata*, which your correspondent from Texas describes as such an attractive shrub, is hardy in Germantown. Last winter it had not the least covering, and it was not injured a particle. I have no doubt that if set in a clump of evergreens which would protect it, it would live out still farther north. The China tree has also attained sufficient size here to bear flowers and fruits. Many southern trees only need to be protected for a few years, after which they can take care of themselves. A further example of this is shown in two plants of *Halesia diperta*, which came from Kentucky. For several years in succession they were partly winter-killed, but for some years past they have not been injured, and now they flower and bear seeds every summer.

Germantown, Pa.

Joseph Meehan.

Meehan's Halesia.

To the Editor of GARDEN AND FOREST:

Sir,—I have often thought that the word "never" is a dangerous one for horticulturists or botanists to use. In the notes I furnished to Professor Sargent regarding *Halesia tetraptera* Meehani, which was figured in your issue of November 9th, it was said to be sterile or, at least, that we never found more than two or three seeds on the tree. That was true up to the present year when, as if to contradict me, the tree has borne, in the language of my foreman, a "soap-box full of seeds." Last year we had three seeds which were sown, and one of these grew this spring, and, so far as I am able to judge from the leaves, it is in every respect a normal *Halesia tetraptera*.

Germantown, Pa.

Thomas Meehan.

Gardening Beside a Hot Spring.

To the Editor of GARDEN AND FOREST:

Sir,—An interesting use of the water from some hot sulphur springs is being made by the Stanford family in Alameda County, California. One of the landmarks of the region is Mission Peak, at the base of which the Spanish settlers founded the old mission San José. One reason why the padres chose this place was because there was a fine group of hot sulphur springs, a few miles south, within easy reach. In fact, the mission would probably have been located at the latter point if there had been a large stream of cold water there. After the American occupation, a famous hotel was built at the "Warm Springs," and large numbers of guests came there by stage. The old register is full of the names of noted politicians and other celebrities of thirty years ago. Governor (now Senator) Leland Stanford purchased the ranch, and a few years later it became the property of his brother, the late Josiah Stanford, whose family make it their summer home. The great hill pastures have been transformed into vineyards of extreme productiveness and value, the district being "on limestone," and frostless.

But the particular attraction at the old "Warm Springs ranch" is now the use that is made of the surplus water. The temperature as it issues boiling from the cement-walled springs is about eighty-five degrees Fahrenheit. The supply is so great that, a few years ago, the owners began to irrigate the orchard, the garden of vegetables and the pleasure-grounds on the slopes of the hill. Everything flourished marvelously. The sediment was abundantly deposited along the channels, to be turned under by spade or plow, but no evil effects followed the use of the water.

Next, a large cement reservoir, low and broad, was constructed on the lawn, with small jets, and a fountain in the centre, and an attempt to grow Water-lilies was commenced here. The family grew interested, and Mr. Josiah Stanford, Jr., soon extended his experiments, until he now grows twenty-five or more species of the best aquatic plants that he has been able to procure. The water-tanks are not roofed over with glass, or in any way protected during the winter season.

Of the native American aquatics, Mr. Stanford grows *Nymphaea odorata*, *N. flava*, *Orontium aquaticum*, *Pondeletia cordata*, *Sagittaria variabilis*, *Nuphar sagittifolia*, *Nelumbium luteum*, and a number of other species and sub-species. Of the exotic aquatics, he has *Nymphaea Devoniensis*, *N. cœrulea*, *N. Lotus*, *N. dentata*, *N. scutifolia*, the pink Japanese *Lotus*, the large White *Lotus*, *Nymphaea cyanea*, *Trapa bicornis*, or Water-nut of China, *Nelumbium speciosum* of India, *Papyrus antiquorum*, some of the *Richardias*, the large white Australian Water-lily, and some other species whose names I have not obtained.

He received three plants of the *Victoria regia*, grown at the Golden Gate Park, San Francisco, but this Lily is very hard to move, even when small, and they soon died. He expects, however, to grow it from seed, and there seems no reason to doubt his success, as a temperature of from eighty to eighty-five degrees, Fahrenheit, can easily be had in the water. I should judge that the sheltered ravine in which the warm springs are situated would never be colder than sixty-five degrees at night, and, all things considered, Mr. Stanford will probably succeed with his giant Water-lilies.

It is to be remembered that the warm springs are less than forty miles from San Francisco, in a district where the deciduous fruits compose the bulk of the orchards. Olive, Orange and Lemon-trees are planted to some extent along the valley's rim, near the hills. The springs seem to raise the temperature, and modify the climate of a small area about the mouth

of the ravine, so that it is difficult to limit the horticultural possibilities here. The water-supply is large; a number of greenhouses could be heated by pipes, and the warm southern exposure, if terraced, would serve for a whole series of winter houses for the forcing of flowers for San Francisco. Any gardener can appreciate the comfort of having a constant flow of eighty-five degrees water, summer and winter, in a California climate. Of course, the temperature lessens in the lower tanks to eighty degrees, seventy-five degrees and seventy degrees, or thereabout, but it is eighty-five degrees many yards from where it breaks forth from the mountain.

Berkeley, Cal.

Charles Howard Shinn.

Notes.

Grape vines can be pruned any time after their leaves fall until late in February, but for many reasons it is best not to delay the work until very cold weather. When it is done on a comparatively warm day, it is not only more comfortable for the pruner but better for the vine.

The *Canadian Lumberman* says that in a warped board the convex side of the curve is always toward the heart of the tree. The warping is due to unequal shrinkage, and it is easily understood therefore why the middle plank is less subject to this trouble than cuts from the other parts of the log.

The thirty-eighth annual meeting of the Western New York Horticultural Society will be held at Rochester on the 25th and 26th of January. No one interested in horticulture, and especially in fruit-growing, can listen to the reports, papers and discussions at these meetings without pleasure and profit.

A dendrological society has recently been organized in Germany under the presidency of Baron St. Paul. Its object is to promote the scientific study of trees. Meetings are to be held regularly, and a journal specially devoted to this branch of botanical science, which every year is growing in importance and interest, is to be founded.

The one hundred and eighteenth volume of the *Botanical Magazine*, which closes with the number for December, is dedicated to Mr. Henry Trimen, Director of the Botanic Gardens of Peradeniya, in Ceylon, which "he has maintained in their former and admired condition," and which, under his able management, "have been greatly advanced in beauty, utility and scientific importance."

Professor J. T. Rothrock has given up his active work in the Biological Department of the University of Pennsylvania, and as general secretary of the Pennsylvania Forestry Association will use his best efforts to excite the interest of the people throughout the state in forestry, and to unite its citizens in efforts to preserve such forests as now remain in the state and to encourage propagation of new growths of timber.

When house plants are accidentally frosted, they should be dipped into cold water or, if too large for that, they should be sprinkled with cold water and then set in total darkness. Under such treatment many of them will come out in two or three days as fresh as ever. Of course it is better that they should not be allowed to freeze, and it is a good plan to roll the stand away from the window on cold nights, or to fasten several thicknesses of newspaper between the plants and the window.

A recent issue of *Le Journal des Orchidées* contains the portraits and descriptions of two remarkable plants recently exhibited from the collection of Monsieur G. Warocqué at the fortieth meeting of L'Orchidéeenne at Brussels. The first was a marvelous specimen of *Cypripedium Harrisianum*, the first artificial hybrid *Cypripedium* which flowered in Europe. It measured more than four feet in diameter and carried ninety-four flowers. Not less remarkable was the specimen of *Cattleya Warocqueana* with sixty-four flowers in four, five and six flowered clusters.

At the last meeting of the Montreal Horticultural Society Mr. John Perrin, in a paper on the "Culture of Mushrooms in Winter," recommended that light sheets of paper, such as newspaper, should be spread over them as soon as the clumps appear, and that they should be syringed lightly two or three times a day. Under this treatment they grow faster, become larger and weigh more, having perfect form and color as well as improved flavor. If allowed to become to any extent dry and discolored by the air, they at once acquire an unpleasant taste similar to that of meat which has been too long exposed to the air.

A writer in the *New England Magazine*, in speaking of the Sahara, says that however barren it is in summer the soil is so rich that the day following a rainfall wild Grass will be observed growing, especially in the depressions, but the sunshine in a day or two will soon scorch it. The general surface of the Sahara, although parched and fiery in summer, wears a mantle of green on all places uncovered by arid sand after the first autumnal rainfall. It keeps green all winter, and from that verdure the Bedouins derive their only means of life, the food of their numerous herds of cattle, which is the only tribute which that immense waste pays to humanity.

A correspondent of the *American Florist* writes that a grower of Carnations near Nashville, Tennessee, sets his plants in the open ground in baskets about four inches in diameter made from common wire fencing with a two-inch mesh. The baskets are made by cutting the fencing into strips about twelve inches long and four inches wide, bringing the ends together and folding one end in. Small plants are set out in these baskets in the spring, where they remain in the open ground all summer, and in the autumn the basket is lifted with the plant and transferred to the greenhouse bench. The plant thus has the advantage of being bedded out constantly and is always transplanted with a good ball of soil.

Monsieur Edward André, the distinguished landscape-gardener of Paris, has been appointed professor of the architecture of gardens and greenhouses at the *École Nationale d'Horticulture* at Versailles. The new course will include theoretical and practical instruction in the art of designing and constructing gardens and parks. Excursions will be made under the direction of the professor in order that the students may be able to see the best examples of the different styles of landscape-gardening. This is the first time that a chair specially devoted to furnishing instruction in this art has been created, and Monsieur André has the honor of being the first professor of landscape-gardening. Systematic instruction in this most important of all branches of the gardener's art could not have been entrusted to a more able, learned and experienced practitioner, and other schools and universities will do well to follow the example which has been set for them at Versailles.

The following list of fragrant Chrysanthemums is given in an English paper: Chryssippe, an incurved flower of bright rosy purple edged with white; the standard old Cullingfordi, a reflexed variety and one of the best crimsons; Dr. Sharp, another reflexed kind, amaranth-purple in color; Exquisite, a pure white single-flowered kind with long narrow florets; Faust, bright purple and incurved; Gus Harris, a single flower with bright lilac florets; Annie Manda, a beautiful hairy variety of pure white; Mrs. Langtry, a pale rose; Nymphæa, a single white kind with florets incurving with age, and Progne, having deep purple flowers of medium size with reflexed florets. The last is pronounced the best Chrysanthemum in cultivation for fragrance. It blooms profusely and the odor resembles that of the Violet. The fragrance of some others is agreeable but indescribable, except in Dr. Sharp, which somewhat resembles that of Progne, and Gus Harris, which is Hawthorn-like.

Bulletin 44 of the Cornell University Experiment Station is devoted to the Pear-tree psylla, which suddenly appeared early in 1891 in many widely separated portions of New York and the neighboring states, and destroyed thousands of dollars' worth of fruit and many valuable trees. It was not a new pest here, having been imported, probably, as long ago as 1832 from Europe. No doubt it has been slowly increasing in numbers until, under favorable opportunities, it all at once worked immense damage. This year the insect did little injury in the orchards which it devastated last year, but it is an enemy against whose attacks pear-growers must ever be on the alert. They should examine their orchards just when the leaves are expanding, and if the nymphs are numerous the trees should be sprayed at once with the kerosene emulsion. A second and third spraying will be profitable if the attack is serious, and especially if but little rain falls to wash off the honey-dew. The destruction of the nymphs is practicable during a period of about two weeks in the middle of May, and a thorough spraying then will so discourage them that little attention will be needed later in the season. Most of the damage is done before the middle of June, but spraying after this date will decrease the number of insects from which the hibernating forms are produced, and the orchard may be saved from a severe attack the following year. The pamphlet contains twenty-five pages, and will be found very complete and interesting as well as instructive and useful to every one who has a Pear-tree.

Road-side Shrubberies.

SO much has been written of late concerning rural roads and road-sides that the paramount importance of the subject can alone justify further reference to it; but we are convinced that there is hardly one reform which would add more to the comfort and pleasure of life in the country than a general improvement in the smoothness and solidity of its road-beds and the attractiveness of its road-borders. Only a fortnight ago we took occasion to speak of the needless defacement of scenery caused by the building of railroads, the opening of mines and the working of quarries, not to speak of the disfigurement of picturesque rocks and other prominent objects by the paint-brush of the advertiser's agent. One of the most flagrant offenders in this way, however, is the path-master, who, under the existing laws of most of our states, is invested with limitless power of destruction when the farmers of his district assemble to work out their road-tax. It is not probable that one path-master in a hundred ever gives a thought to the actual beauty which he destroys or to the possible beauty which he neglects to develop in his work, and yet the road-sides are directly under the eyes of the people more continuously than any other part of the country. These same road-sides, too, furnish unrivaled opportunities for producing beautiful effects with grass and flowers and foliage, so that the sins against good taste which are here committed are almost universally prevalent and of a most aggravating quality.

If any one in the course of business, as a manufacturer, for instance, violates the sensibilities of his neighbors by poisoning the air with noxious or offensive odors he can be prosecuted for maintaining a nuisance. In the same way, if he offends by disturbing noises, he is also liable to indictment. Certainly, the sense of sight should be protected from out-

rage as well as the sense of smell or of hearing, and there is no sufficient reason why the public should not be protected from the depression and annoyance which comes from the destruction of natural beauty. Now, there are many road-sides where a thicket of shrubs or a natural growth of trees and vines should not be allowed to remain. No one can drive through the best portions of the farm-lands of Lancaster County or Bucks County, in Pennsylvania, for example, without noting the beautiful effect of the green-sward as it flows smoothly under the open fences from the grain and pasture fields and across the road-border to the very edge of the wheel-way. A weed or clump of bushes here would look as much out of place as it would in the adjoining meadows. But in large sections of the middle states and of New England, where the land is rough, and where the fences are often of stone, nothing could be more beautiful or harmonious than the natural growths which nature so bountifully provides. When this border of shrubbery is cleared away and burnt off, nothing is left above the blackened ground but the stumps, bare rocks and raw banks, so that a desolation is made of this verdurous wall, which always looks, when left to itself, cool and beautiful, and has a fresh interest every rod.

The illustration on page 617 is simply a passage in a typical Berkshire County road in Massachusetts, from a photograph taken by Mr. G. S. Olmsted, of this city. This road winds its way beside a roaring stream through woods and thickets, with vistas opening here and there to give the view of some distant mountain-range or a nearer view of rolling pasture-lands, but it furnishes constant delight to the eye and food for the imagination. Of course, a road-side should not be made a breeding-ground for larval pests or a nursery of plant-diseases. Trees which naturally support injurious insects, or which invite the attacks of black-knot and other fungi, should be cut away just as they should if they were inside the farm-fences. But as the road winds from meadow to upland, through hollows and over ridges, offering every diversity of soil and exposure and degree of moisture, a place will be found for all of our best native shrubs and trees and festooning vines and herbaceous plants, and the richness of our flora will ensure endless variety. There are few road-sides in the more rugged and hilly portion of the country which could not, with a little care, be made objects of beauty, winter and summer, fragrant with flowers in their season, and vocal with the songs of birds.

Our National Parks and Forest Reservations.

THOSE portions of the annual report of the Secretary of the Interior which refer to the national parks and timber reservations are not reassuring. We are told, for instance, that a visitor to the Yosemite will pass through a forest within the limits of the National Park, upon which a private individual has some claim, and here he will see magnificent Pines, five feet in diameter and from a hundred to two hundred feet in height, being cut down simply to utilize some twenty or thirty feet of the trunk for shingles. He will find also that the Commissioners have never taken any counsel with an expert engineer or landscape-gardener for the purpose of making a thorough study of the valley and adopting a systematic plan of improvement which could be carried on through years; but, on the contrary, they are making spasmodic efforts to "underbrush" the valley without any regard to the natural beauty of the place. No destructive fires have occurred here this year, but there is little guarantee of future safety, since the penalty for starting a conflagration is nothing but a fine. The foreign sheep-herders, from whom the danger largely comes, have no money, even if they were convicted, and the damage from fires might be incalculable. In the Sequoia Parks the ground is covered with fallen timber, which is dead and dry, and the forest-floor is so inflammable that a fire would work immense destruction. The Portuguese and Mexican herders pastured 500,000 sheep last summer in the Kern and King's River valleys, mostly on Govern-

ment land, for which the owners of the sheep paid no rent nor taxes, and these immense herds devour everything in the way of vegetation. The difficulties in the way of restraining these cattle and sheep-herders from trespassing on the reservations are discouraging, and until the parks are surveyed, the boundaries distinctly marked, and penalties provided against lawlessness, these forests are in constant danger.

The vandalism of tourists is complained of in the report on the Yellowstone Park. Poachers have settled all around it so that the game has no adequate protection. There are four hundred buffaloes on the reservation, and a few moose in the southern part, but as they roam beyond the line they are in danger of extinction. There are several large bands of mountain sheep here, too, but as their finest range is north of the Lamar and Soda Butte Creek they will disappear if that portion of the park is cut off in accordance with the bill for establishing new boundaries which is under consideration by Congress. The Secretary, for this and other reasons, opposes this so-called segregation project, and advocates the passage of an act defining the boundaries of the park as they now exist, including, however, the timber reserve added by the President's proclamation. Some strong arguments against the surrender of the north-east portion of the park to the Cooke City lobby are set forth in the issue of *Forest and Stream* for December 8th. We have already spoken of the fact that six forest-reservations, including three and a quarter million of acres, have now been established under the new law, and this beneficent policy will probably be further carried into effect, but unless the reservations are protected by detachments from the army, as has been done in the Yellowstone Park and the Sequoia Park, there is no way to save them from the depredations of thieves or the still more sweeping desolation by fire.

The sum of it all is that we have set apart from the public domain certain tracts for national parks and forests, but their boundary-lines have never been defined, and no law has ever been enacted which establishes a system of government within their limits with appropriate executive machinery and prescribed penalties for the violation of its provisions.

Picturesque Names for Flowers.

MRS. FANNY D. BERGEN has contributed to the *Journal of American Folk-Lore* a valuable and interesting collection of popular plant names that are found in America, showing that wherever people live in close contact with nature, there arises a pleasant homely sympathy with floral growth, that results in names which are often agreeably descriptive of some quaint look of the flower, or of its practical uses.

In England the common flowers all have names endeared to us by inheritance, and often embalmed in poet's verse; and in our own land, while we keep many of the dear old terms, others have grown up among the country people or the children, that are often equally happy and appropriate.

These names Mrs. Bergen has with much pains gathered together in a pamphlet, which is full of interest to the reader who loves the simple blossoms that carelessly adorn our roadsides and meadows, or are cultivated in the cottage garden-patch. Indeed, it makes us wish that the new and splendid blossoms which the skilled gardener's care is ever producing might be equally inspiring to the florist, so that the glory of Chrysanthemums, for instance, with their wealth of color and luxuriant form, might be known to us, as they are to the Japanese, by delicate and suggestive appellations, rather than by the tiresome complimentary names of people, which are without significance or beauty.

Our oriental brother, who loves his garden, and delights in this splendid opulent blossom of the fading year, lets his poetical fancy revel in the suggestions of these many-tinted florets, and, like a lover, finds fanciful and tender names to describe these curled darlings of the parterre, such as Silver World, or White Dragon, or Companion of the Moon, which fitly convey the snowy glories of some great white blossom. Again, he calls one varied yellow flower Golden Brocade; a paler golden one, Dye of the Dew; a dull red beauty he entitles Shadows of the Evening Sun; another, with a tinge of orange in the

carmine, is Moon's Halo; a third, which glows afar, is Beacon Light; a fourth, with linings of yellow to its maroon petals, he styles Leaves in Frost. For a soft globe of dubious hue he finds the descriptive term Thin Mist; a pale pink he calls Sky at Dawn; another white one lives before us with its myriad blooms as Starlight Night, and one, with tangled petals wildly straying, he styles Disheveled Hair; while for a glowing flower of vast proportions, Terrestrial Globe is not too comprehensive a term to his charming imagination.

Contrast these poetical and delicate descriptive titles with the prosaic lists of the nurseryman, with his Mrs. John Smith, and Abijah Jones, and Hezekiah Brown, or their equivalents, to degrade these royalties of the garden from their high estate; and mark the difference between a sensitive and poetic people, who truly love a blossom, and the unimaginative, hard-headed Anglo-Saxon who trades in herbaceous plants.

But when quite out of heart with the lack of appropriateness in the catalogues of Roses and Pæonies and Lilies that we are yearly compelled to study, it is pleasant to take up this little list of Mrs. Bergen's and see what our people will do when let alone.

Here are found such pretty names as Cups of Flame for the gay *Eschscholtzia*, and Eye-bright for the *Drosera rotundifolia*, which is more closely translated in our botanies as Sun-dew, from its shining exudations. In Canada they call the Red *Lychnis* Scarlet Lightning; in Ohio, Fireballs. In some places the *Claytonia*, or Spring Beauty, is known as Good-morning-spring; in Massachusetts the *Argemone Mexicana* is Bird-in-the-bush, and *Silene Armeria*, None-so-pretty, while the explosive Jewel-weed, or Touch-me-not, is Kicking-colt, and the *Polygala paucifolia* is Babies'-toes. The pretty names for the starry *Houstonia* are numerous, and so charming one scarcely knows which to choose. Blue-eyed Babies, Quaker Ladies, Angel Eyes, Innocence, Nuns, Bright Eyes, are all appropriate, and there are more besides. There is no sweeter name for the Pansy than the old-fashioned New England one, Lady's Delight, but all through the middle states one hears of it only as Johnny-jump-up. In North Carolina the children call the Violets Rooster-hoods, probably the same variety that some of our botanies recognize as Hood-leaved Violet, from the curl at the bottom of the leaf. The omnipresent Life-everlasting is in northern New York called Feather-weed, because it is used by poor people to fill beds when feathers are lacking; and here in Hingham many people call them Pincushions, from their round ball-like effect, with tiny black spots like the heads of pins scattered over them.

The Chicory's azure blossoms are called Blue Sailors in Brooklyn, New York; the *Chimaphila umbellata* is known in Maine as Love-in-winter; the *Monotropa*, with its spectral white pipe, has the fitting name of Ghost-flower in New Brunswick, and the *Castilleja coccinea*, with its scarlet-painted cup, is in the west called Prairie-fire, and in Massachusetts, Indian Paint-brush, or Red Indians. *Euphorbia marginata* is known in New Hampshire and Nebraska by the picturesque name of Snow-on-the-mountains. Whether this is the flower that inspired Dante Rossetti's tragic little verse with its recurring refrain,

The Wood Spurge hath a cup of three,

I know not, but the poem has added a poetic interest to all the Spurges.

In some New England towns the fragrant Bayberry, with its gray-blue fruit, is known as the Candleberry, from the use made of the wax that exudes from it, which, obtained by boiling, makes a tallow fit for candles. The wild Orchids, with their suggestive shapes, are always fruitful in descriptive names. Lady's-slipper, Whip-poor-will Shoes, Dragon's-mouth, Nerve-root, Dragon's-claw, Coral-root, Adam and Eve, Ladies'-tresses, Ram's-head, are all applied to different members of this curious family.

Yucca filamentosa, with its sharp points and hairy filaments, is known in Massachusetts as Thread-and-needle, and in Texas as Eve's Darning-needle. For some unknown reason, similar, no doubt, to the one which causes that

Il n'y a pas un âne en toute la France
Qui ne s'appelle pas Martin,

all the *Trilliums* in New Brunswick are called Benjamin, sometimes with the addition of an opprobrious epithet referring to their odor. In Wisconsin this beautiful Wake Robin is called the Trinity Lily. In New England *Trillium erectum* is recognized as Bumble-bee-root, or Squaw-root. We all know the significance of Jack-in-the-pulpit, but the same *Arum* is known as Indian Cradle, from a fancied resemblance to a papoose with the hood drawn over its head, and also as Dragon-root and Lady-in-a-chaise.

To the Fungi all sorts of superstitions attach. One kind is called Devil's Umbrellas, another Death Baby; this latter deemed so ominous that people rush out and exterminate it when it springs up in the yard, as it is thought to be prophetic of death. The Algæ, too, with their uncanny forms, have names of evil import, such as Devil's Apron, Devil's Apron-strings, and the like. It is impossible to quote from Mrs. Bergen all the various names that popular fancy has attached to its familiar friends of road-side and garden, but they show that living interest in the flowers about them which the man of science and the gardener, with all their keen interest in a new variety, too often lack.

While it is necessary to have Latin and Greek names, which are universally intelligible, for plants, we have a right to ask also, for our common use, something from the florist which shall bear the same relation to our understanding that the classic names did to those who gave them. The Greek did not name his flowers in Sanscrit or Coptic, but in his own tongue. His word Anemone, for the Wind-flower, was a thing of meaning to him, not merely a noun. His name for the Poison Hemlock, Koneion, from konos, a top, which was significant of the dizziness and whirling that resulted from its use, bore with it a warning to the incautious. The Beech (Phegos) he named from its edible nut; the Yew (Taxon), from the bow and arrow, for one of which it furnished the wood, for the other the poison. The Chestnut was called after the Thessalian town, in which it grew to splendid size. The name Walnut bore reference to the round shape of the nut. The Plane Tree's appellation characterized its large broad leaves. He called his Coriander after a pungent insect on account of the smell of its leaves; his Parsley from the stones amid which it grew; his Celandine bore the name of the swallow, with which it came and fled. The Cedar, which was the fragrant wood burned upon altars, was named from the word which meant sacrifice.

So also the Roman names of trees are significant. The Maple was called Acer, perhaps from its sharp-pointed leaves, though some authorities say it was so called because its tough wood was employed for the handles of pointed weapons, spears, javelins and the like.

The Poplar, from its planting along the public-ways, was called Populus, the people's tree. Their names for the Walnut (Juglans) signified Tree of Jove, from its majestic proportions. The title of the Palm bore reference to its hand-shaped leaves; that of the Cypress, to the island of Cyprus, where the altars of Venus were adorned with its evergreen boughs. From their northern conquests the Roman legions brought back not only trees, but their names—the Birch, the Willow, the Pine and Fir all bearing Celtic names significant mostly of their use or place of growth. Salix came from two Celtic words signifying near water; Pinus, from the rocks and mountains, where it made its lofty home; Carpinus, from *car*, wood, and *pino*, the head, alluding to its use for making yokes for cattle. Quercus is from the two Celtic words, *quercues*, signifying noble tree, because the Oak bore the sacred Mistletoe. The Druid title for Oak, *deru*, lives still in their own name, which is derived from it, and at every turn we find an interesting significance in the terms which preserve at once to us the history and the habits of an ancient people.

There is no reason why Americans should not name their own flora in a way to be equally valuable to succeeding races in the far-off future. We lack neither imagination nor poetical feeling, though very little of either seems to find its way into professional nomenclature. It is a pity that some nurseryman or florist should not distinguish himself by finding fitting nouns to portray the glories of his magnificent fruits and flowers, and the prizes offered for the best name for a new Tomato or Grape are efforts in the right direction. Still, our Chrysanthemums and Roses have reached a much higher development in size than they have in epithet. Therefore, I make a plea in their behalf that henceforth some attempt may be made to render them as interesting in name as they are in nature.

Hingham, Mass.

M. C. Robbins.

A. Few Texas Shrubs.

I HAVE been trying in my garden a few of the shrubs which are native to this region and which will prove hardy in most of the southern states. Some of them are truly ornamental, and all have flourished without unusual care or cultivation.

Chilopsis saligna, generally known as the Flowering Willow, is a native of the south-western part of Texas, and is already found in many gardens. It grows from ten to fifteen feet high, and the large flowers in terminal racemes stand well out from the mass of narrow leaves. These flowers, in shape like those of the Catalpa, are pink, with a broad darker spot

and a yellow marking on the lip, and at night they exhale the odor of sweet Violets. The whole shrub has the appearance of a dwarf Willow, and its beautiful flowers are borne abundantly all summer long in spite of dry or hot weather. It grows well in a sandy or a limestone soil, and is readily propagated from cuttings as well as from seeds, which are borne in long pods like those of the Catalpa.

Acacia fragrans grows wild on many rocky bluffs west of the Brazos. The only one I have raised, however, flourished on limestone soil. The foliage is elegant, although a little thin, and the delicate pink and very fragrant flowers are carried in round heads. They generally appear in April, and keep opening until autumn. I remember to have seen one of these shrubs in Brown County which was in bloom before the leaves were fairly developed, and it was a solid mass of pink some five or six feet high. In the same region grows Rhus microphylla, a shrub whose small and greenish flowers appear before the leaves in spring. The bright orange-colored fruit contrasts pleasantly with the fine green of the foliage, but I can hardly recommend the plant except for variety.

Lippia lycioides, another shrub of the same region, prefers sandy soil, and it may attain the height of ten feet when well developed, though it is generally more dwarf. The grayish leaves are small, and the flowers, borne in a multitude of racemes, are white and very small. The whole appearance of the shrub is not showy, but it blooms perpetually, and the flowers are so sweet-scented that it certainly deserves a space in the garden.

Rosa setigera, var. tomentosa, grows wild in swampy woods, but it makes itself perfectly at home on dry upland. It is a straggling half-climber, and, as I have it covering a stretch of rumbling old stone wall, it is a beautiful sight in May; but, unfortunately, its bright pink flowers appear but once a year.

Cæsalpinia pulcherrima is a small shrub which one often sees in Texas gardens. The compound leaves are very elegant, and the large flowers are borne in great terminal racemes. They are light yellow, and the crest of scarlet stamens with which they are crowned adds very much to their beauty. The pods are large and flat, and contain a few large seeds, which germinate very readily. It blooms abundantly, but it is not perfectly hardy here.

Dallas, Texas.

J. Reverchon.

What Plants may become Weeds?

SO many cultivated plants escape to become troublesome weeds, when the soil and conditions are favorable, that it is necessary to inquire what attractive plants may safely be introduced into cultivation? Protests have been made against such species as Calystegia pubescens, Apios tuberosa and Helianthus divaricatus being offered by nurserymen. There may, however, be localities where not any of these would, under the best treatment, become weeds. I have had much difficulty in growing Apios tuberosa in some soils. Generally, I believe, the worst weeds we have are not indigenous, but are introduced directly by cultivation, or with cultivated plants, and soon become acclimated, and thrive better than other plants already established.

Sedum Telephium (common Live-forever) is a dreaded weed when it gets into a meadow or cultivated field, but I have seen it established in a sterile spot on a rocky road-side for twenty years, with no apparent increase. Left entirely to itself, it grew and flowered, without spreading, so luxuriantly as to suggest its usefulness in covering barren places where little else would thrive. Five years ago a neighbor found in his pasture a small patch of the Venus Paint-brush (Hieracium aurantiacum). I warned him of its inclination to spread in our Vermont soils, and at that time a dollar would have eradicated it. He had no fears of it, however, until two years later, when he found it had scattered itself over a good portion of his farm. He has since spent nearly two hundred dollars in digging and plowing it under, and the end is not yet. Our soil and climate seem to have just suited it, or to have modified it so as to suit the soil and climate, for in some localities good farms have been overrun with it, and on stony or other rough pastures, where the plow cannot be used, it is master of all. It is a common species among the flower-seeds of foreign catalogues, and I presume is offered by Americans, too. It, perhaps, seldom finds so congenial a soil as ours, for here it not only multiplies by its underground stolons faster than any tame Strawberry I ever saw by its runners, but its seeds all seem to mature and are scattered far and wide by the wind.

The common Virgin's Bower (Clematis Virginiana) is sometimes a pest in meadows that are mown every year, even crowding out the grass. This occurs, however, only when the soil is light and moist. We often have to coddle it when trans-

planted until it gets a good hold on the soil. In Vermont the shrubby Cinquefoil (*Potentilla fruticosa*) is a local plant usually growing on rocky banks and under cold cliffs; it is seldom more than two feet high, and, I believe, never spreads to any extent; but in some parts of north-western Connecticut whole fields are entirely abandoned to this shrub, where it grows most luxuriantly four feet or more in height in an almost impenetrable mass. The conditions for its development there are most favorable, and it spreads both by seed and roots. But who would discard entirely the Virgin's Bower or the Bitter-sweet (*Celastrus scandens*) from cultivation because they occasionally find locations so favorable to their increase as to become weeds? It would be as reasonable to expect seedsmen to discontinue the sale of the Parsnip or Carrot because they sometimes escape from gardens.

Foreign Correspondence.

London Letter.

PUBLIC PARKS AND GARDENS IN LONDON.—There are 257 public parks, gardens and playgrounds in the metropolitan area of London. Of these eighteen of the most important, such as Kew, Hyde Park, Regent's Park, Richmond Park, Epping Forest, etc., are maintained by the Crown, that is, out of general taxation, fifteen by the Corporation of London, 108 by local authorities, and fifty by associations, the clergy, etc. The remainder are now controlled by the London County Council. Besides such important open spaces as the Thames Embankment, Hampstead Heath and Parliament Hill, the area governed by the County Council includes the large parks of Battersea, Victoria and Finsbury, the whole being about 3,000 acres in extent.

Efforts are now being made to add considerably to these open spaces, and to place the whole of them, except those controlled by the Crown, under the management of the London County Council. While some of these open spaces are laid down with turf and paths, and planted with trees and shrubs, in the usual gardenesque fashion, others are handed over to football, cricket and similar games. Some are little more than large school-yards, in which children can romp and find healthy open-air exercise. There are many influential bodies and individuals who make it their duty to see that these open spaces shall be available for recreation, so that even the poorest children and adults can here enjoy a breath of fresh air. London is well enough supplied with large parks, but she still requires a large number of small gardens and playgrounds, more especially in the crowded districts. Excellent work in this direction is done by the Public Gardens Association, who purchase and lay out available pieces of ground and then hand them over to the care of the local or other authorities. It is impossible to overestimate the value of this work of providing suitable and convenient recreation and breathing-spaces in all large towns. It is coming to be generally recognized that land should be set apart for such purposes when it can be secured at a cheap rate and wherever there are evidences that the population will become crowded.

The London County Council had under consideration some time ago a proposal to appoint a superintendent of all the parks and open spaces under their control at a salary of £700 a year. For some reason this fell through, and recently they have appointed a superintendent at £500. It is disappointing to horticulturists that the County Council should have selected for this office a man who has hitherto held the post of assistant architect. In England the architect and the landscape-gardener do not, as a rule, agree in regard to the laying-out of gardens. At the same time we pride ourselves on the high art displayed in the construction of many of our gardens. To make the matter still more surprising, the County Council now advertises for a gardener to act as assistant to the architect at a salary of £300 a year. This, remarks the *Gardeners' Chronicle*, "is a triumph for the architects and a humiliation to the landscape-gardeners."

The sudden death of the Duke of Marlborough, at Blenheim, a fortnight ago, has resulted in an arrangement for

the sale, by auction, of the very extensive collection of plants which the late Duke, who was an enthusiastic horticulturist, had formed during the past ten years. Until about two years ago the collection of Orchids at Blenheim was the largest in point of numbers of any private collection in England. Latterly, however, many of the Orchids have been disposed of and replaced by Roses, Carnations, etc. Even now, there remain 25,000 Orchids, beside enormous numbers of indoor plants of all kinds. The sale is to take place on the 19th of December and following days.

SEEDLINGS.—Sir John Lubbock's latest contribution to science is a large work in two volumes on seedlings. He states in the preface, "The germination of plants is certainly not the least interesting portion of their life-history, but it has not as yet attracted the attention it deserves. . . . Under these circumstances, it seemed to me that the subject was very promising, and it was evident that Kew would afford unrivaled opportunities for such an investigation." The vast number of illustrations of seedlings, and still more numerous descriptions of others, nearly every one of which was prepared from living examples grown at Kew, prove that Sir John has made the most of the opportunities Kew offers for work of this kind. Enormous numbers of plants of every description are annually raised from seeds received at Kew, a large proportion of which either fail to thrive or are wanting in those characters which would render them suitable for artificial cultivation. Consequently many of the seedlings figured and described in Sir John Lubbock's work are of plants which probably could not be seen anywhere in the seedling stage except at Kew. The work has been in progress since 1885, when a young gardener with an aptitude for drawing was selected from the Kew staff for the work required by Sir John. This book will, no doubt, prove of considerable service to botanists of all kinds. It contains illustrations and descriptions of seedlings of nearly all the natural orders, and in many cases of numerous genera in each order, of Phanerogamous plants.

CANNAS.—The important position now occupied by these plants is due to the new race of dwarf, large-flowering, richly colored kinds which has been obtained recently, chiefly by Continental growers. The genus *Canna* has long held a place among garden-plants, but, except for their foliage, they were not of much decorative value, in England, at any rate. *C. iridiflora*, generally called *C. Ehemanni*, was the first large-flowered kind to attract general attention; this was about ten years ago. The history of garden Cannas remains to be told. The Royal Horticultural Society has, therefore, been fortunate in securing the services of Mr. J. G. Baker, F.R.S., for this purpose, and he will read a paper on Cannas at a conference of that society to be held next year. Mr. Baker is certain to do the work thoroughly, but, at the same time, it is likely to prove troublesome. There are something like a hundred specifically named Cannas in gardens, and probably these will be rendered down by Mr. Baker to about a dozen good species. The genus is represented in the Old World only by the Indian Shot (*C. Indica*), and in tropical America by twenty or thirty species. Mr. Baker will be grateful for any specimens or information of any kind relating to Cannas, and more especially to the garden kinds. Plants for cultivation and observation at Kew will also be most acceptable.

I may mention here a new hybrid *Canna* figured in the *Revue Horticole* this month, page 540, which was raised by Monsieur Maron from the tall white-flowered *C. liliiflora*, crossed with one of Monsieur Crozy's large-flowered seedlings. It is named Madame J. Sallier, in compliment to the wife of Monsieur Sallier, the Paris nurseryman, who holds the stock of this hybrid. It is tall in stature, the flowers are very large, and arranged on the spike not unlike those of *Gladiolus Breuchleyensis*; their color is rich crimson, with yellow marks and shading.

TACSONIA SMYTHIANA.—This is figured and described in the *Gardeners' Chronicle* as a new hybrid which origi-

nated in the gardens of Basing Park, *T. mollissima* and some other species of *Tacsonia* being the supposed parents. It has trilobed, serrated, dark green leaves, conspicuous ciliated stipules, and long-tubed flowers. The calyx is over an inch long, five-lobed, split on one side, and the cylindrical corolla tube is five inches long, the limb three inches across and formed of ten oblong segments. The color of the flower is rosy salmon. I have compared a fresh flower of this so-called hybrid with *T. mollissima*,

by Mr. Robert Templeman, of Cape Town, in 1887, and named by Mr. Baker, who describes it as having linear, rigid, erect leaves, two feet long, and a tall, branched scape of bright red funnel-shaped flowers, over an inch long, with spreading segments. Corms of this plant have lately been sent to Kew by Mr. Templeman. The leaves are similar in texture and form to those of *Sparaxis pulcherrima*, now called *Dierama*. The corms are remarkable in being persistent—that is, the old corm, instead of shriveling

Fig. 105.—Roaring Brook Road, Sheffield, Massachusetts.—See page 613.

and find that there is very little difference indeed between them except in color—*T. Smythiana* being a shade darker. *T. mollissima* is an old garden-plant which is sometimes called *T. manicata*, a different species. There is a large specimen of it in the temperate house at Kew, which flowers freely every year. *T. Smythiana* obtained a certificate about six weeks ago.

TRITONIA TEMPLEMANNI.—This is one of the handsomest of the thirty species of *Tritonia* known. It was discovered

and dying away as in *Gladioli*, remains quite firm and healthy, and as a new one is formed every year, the root-stock consists of a number, in some cases more than a dozen, of corms, all packed closely, one on top of the other. The lowermost corms must be a dozen years old. Their appearance is singularly like the droopings of deer.

RICHARDIA AURATA.—This is advertised as a hybrid between *R. albomaculata* and *R. hastata*, raised by Monsieur Deleuil, of Marseilles, and is described as being two feet high,

with hastate foliage, marked with white blotches and well-developed spathes of a beautiful chrome-yellow color. It will have to be very much superior in habit and in the size and color of its spathes to either of its parents, if it is to rival, as some say it does, the two fine yellow kinds named *R. Elliottiana* and *R. Pentlandii*. Still another new Calla, named *R. Nilotica*, is offered by a French nurseryman, and is described as having white and red spathes. The tubers, which were "collected on the banks of the Nile," are quoted at five francs each by M. Letellier, of Caen.

Cultural Department.

The Formation and Care of Lawns.

AT the late meeting of the New Jersey Horticultural Society, a paper on this subject was read by Mr. George C. Woolson, in which he explained the method of establishing a sward of pure Grass which has been developed by Mr. J. B. Olcott and the Connecticut Experiment Station. Mr. Woolson explained that, no matter how carefully the ground is seeded on the old plan, the weeds will come up more thickly than the Grass, and all the season long much time will be needed in digging out Dock, Plantain, Rib-Grass, Canada-Thistle, and other perennial weeds which will flourish luxuriantly in a soil which has been properly prepared for lawn grass. This preparation of the soil is made by deep and thorough cultivation, so that the roots of the Grass can penetrate in time of drought to damp soil, enriched with well-rotted manure at the rate of forty to fifty tons an acre on poor soil, and a thorough fining of the surface with a short-toothed harrow or a steel rake. The same preparation is needed for the new system which Mr. Woolson proceeded to explain and to illustrate by his own experience, as follows:

A perfectly pure sod of a very fine variety of Rhode Island Bent Grass, *Agrostis alba*, is selected and divided into single plants of one or two spears, and these are set out in rows nine inches apart and nine inches between the rows, or at the rate of sixteen plants to a square yard. These plants are pressed firmly into the soil, and afterward the whole surface is rolled with a hand-roller. All the care required afterward is to keep out every weed, and especially plants of white clover. A small bayonet hoe of a peculiar pattern is used for this purpose. In from three to four months the ground is entirely covered with a short, very thick mass of grass resembling that of a long-piled carpet or fur rug. During the summer an application of from two hundred to four hundred pounds of nitrate of soda to the acre, applied in three or four sowings, will give the plants a fresh start and cause them to assume a bright green hue. If these directions are carefully carried out, there will be no need of weedy lawns and the general complaint that grass cannot be made to grow under the shade of trees.

On the 24th of May, 1891, I set out, along with fifteen other sorts of selected grasses, a patch of the improved Rhode Island Bent Grass, and in three months the plants had spread and grown solidly together, so thickly, in fact, that there was no chance for a weed to obtain a foothold. Again, on the 14th of May, 1892, I set out a larger area, ninety-five feet long and twenty-nine feet wide, which was performed by three men in one day, at a cost not exceeding five dollars. A portion of this last plot was planted under the shade of a large Hickory-tree, with but little expectation that it would do anything more than barely live. In four months, these plants had, in nearly all places, run together and formed a very thick turf of the softest and deepest green I had ever seen, and even under the thickest shade the only difference visible was that here the turf was shorter, showing that the tree had taken from the soil a part of the nourishment provided for the grass. To-day, on examination, I found that the runners of the grass had grown closely up to the trunk of the tree and even in between the large roots which were exposed at the base. This grass, during the past summer, was not cut, and showed but very few flower-stalks. The past summer has been one of unusual dryness, in fact, the driest I have known in twenty-two years, and, as the grass-plot received no artificial watering, it shows conclusively that it will stand a severe drought.

In August I concluded to try another experiment, and so set out a plot of fifteen by nine feet, where from four to six

inches of coal-ashes had been thrown, first, of course, digging the plot over to loosen the mass and the soil below the ashes, which, by the way, was very poor. This plot grew continuously, from the time I set it out, and withstood the hot August and September suns to which it was exposed during the entire day. On September 14, though the drought continued, I set out still another plot, ninety-five by twenty-nine feet, but this time setting the plants six inches apart each way, thinking that they would stand a better chance of living. From September 14 until the latter part of October less than one inch of rain fell, and now the individual plants have grown to a diameter, in many cases, of four to five inches, and should the winter continue open will have nearly covered the ground.

The cost of tending the plot of ninety-five by twenty-nine feet, the past summer, has amounted to not over one dollar per week, while on adjoining plots, sowed with Red Top and Kentucky Blue Grass, the growth of weeds has been enormous and required heavy outlay for labor, and even now there are ten Plantains to every spear of Grass. The whole secret seems to lie in clean cultivation at the outset, as a week's work at that time and a few hours each week for the first summer will accomplish what constant labor could hardly bring about in after years.

Rhode Island Bent Grass, as usually seen, has long runners, with the plants far apart, while in the variety spoken of here the plants cover the entire runners and show no naked stems. Whether this special form of Bent Grass will succeed in California and the southern states remains to be seen, and more extended experiments will be required to settle this. I believe it will pay for farmers to adopt this method of putting down their Grass-fields in some localities where labor is not too expensive. A ready market could be found for pure Grass-seeds at much higher prices than those which now rule. If we wanted a peculiar variety of Rose or Chrysanthemum, Apple, Grape or other fruit or flower, we should not think to perpetuate it by raising it from seeds taken from any of these plants, and we are simply carrying out the same system of grass for our lawns.

I found the action of nitrate of soda beneficial on my own lawn, but any good commercial fertilizer, bone-dust or sheep-manure, will probably do as well, and thus render a top-dressing of stable-manure unnecessary. If the expense of this plan appears too great to warrant the undertaking, it should be remembered that the outlay all comes at the start, and is really less than what is required to make a fair lawn after the first season, while the final results are altogether superior.

Outdoor Cultivation of European Grapes.

IN 1851 Downing said that "the introduction of the foreign Grape into this country for open-vineyard culture is impossible. Thousands of individuals have tried it; the result in every case has been the same—a season or two of promise, then utter failure." It was then believed by our viticulturists that "in the vicissitudes of climate of the North American continent there is something mysteriously hostile to the *Vinifera-vine*."

This opinion had to be modified after the successful cultivation of *V. vinifera* in California, which proved that Downing's judgment might be correct only as it applied to the eastern states. Here the European Vine has persistently failed to thrive. But a few years ago special reasons for this failure were discovered, and not in any mysterious peculiarity of our soil or climate, but in the prevalence of two nearly invisible depredators which are peculiar and native to the eastern regions of North America. One of these foes to the Vine is an insect, *Phylloxera*, or Grape-louse; the other is a fungus, the *Peronospora viticola*, or Grape-leaf mildew.

It will be noticed that since the introduction of these two pests into Europe and into California these regions threaten to become also unfavorable to the open-vineyard culture of the *Vinifera* Grape, and this proves that soil and climate have not all to do with the difficulty in question. In Europe this Vine has flourished in health for hundreds of years, and probably might have continued to do so had it not been for the introduction from America of these enemies. In southern New Jersey twenty years ago all of the varieties of our native Grapes grew and fruited in perfection. It was then thought that here the soil and climate were especially suited to a successful viticulture. These conditions are in no respect altered, and yet now it is evident that all of our so-called hardy native Grapes are doomed to failure in open-vineyard culture unless defended against attack of these pests, which formerly were either unknown or unnoticed.

Fortunately for the future of European viticulture, and of

our own, remedies for both these evils have been found. It is now known that the Phylloxera may be avoided by planting the Vine in very sandy soil, or, in case of the foreign Vines, by grafting them on the roots of such native species as are proved to be resistant to the grape-louse. The mildew may be prevented by spraying the Vine occasionally during the season of its growth with some one of the solutions of copper sulphate. In my practice I have had the best results from use of the Bordeaux mixture, a combination of copper sulphate, lime and water. This mixture, when properly made and applied, is durable, and not readily washed off by rains. In ordinary seasons a Grape-leaf well sprayed in June will visibly retain throughout the summer the protecting chemicals upon its surface.

Where the grape fungi are epidemic, the foreign Vine and the native Vine are about equally susceptible to disease. The foreign varieties seem to be rather more attractive to the fungus germs, and the vine may have the merit of dying perhaps a little sooner under its disorders than some of our native kinds. Either sort will succumb to fungi unless protected. In my vineyard were a number of Vinifera hybrids which nearly all perished from mildew when this became epidemic. Had I not known what ailed them I might have fancied that they failed because they could not endure the climate.

When I began experiments in vine-spraying in 1887, a few specimens of these hybrids were yet dragging out a sickly life, but visibly pining away. Under the administration of the Bordeaux mixture they recovered, and are now growing in apparent health. This experience teaches that we may now hope to grow in open vineyard those European varieties which can endure the temperature of our winters. Father Guicheteau, Principal of the French Catholic College at Vineland, has growing on his farm near Millville, New Jersey, some valuable foreign Grapes, brought from France. These Vines have been persistently sprayed with Bordeaux mixture, and Father Guicheteau informs me that they are growing and fruiting as well as they do in the old country, and have continued this good behavior for three years. But for the protection given them by this spraying, they would ere this have surely perished from mildew. The soil in which they grow is very sandy, and hence they escape the Phylloxera. I shall get some of the wood of these vines and graft them on the roots of my Ironclad Grape, which is proof against the grape-louse. Then I hope to show that to successfully grow the Vinifera Grape in our Atlantic states is not impossible.

The beneficial effect of spraying the vine with the copper solutions can scarcely be realized by those who have not practiced it successfully. Many fail in its use from some error in practice, and the published reports of experiences are yet quite conflicting. For instance, it has been reported that my vineyards are as badly diseased as those which have not been sprayed with the fungicides. The summer of 1892 has been favorable to the growth of the vine, and adverse to the growth of the fungi. Under these conditions, some of those who did not spray their vines secured a partial crop of grapes, and a measurably healthful growth of canes. Hence they argue that "The disease is dying out!" and "all of this bother about fungicides is a humbug, invented by the United States Department of Agriculture as an excuse for the institution of the Division of Vegetable Pathology!"

What may be the effect of another hot and humid summer on vineyards infected by the fungi remains to be seen. Under such conditions I suspect that we shall find it difficult to defend the health of our Vines, no matter whether they are native or foreign.

Vineland, N. J.

Alex. W. Pearson.

Irises and Their Cultivation.—II.

THE rhizomatous Irises are increased readily, and usually rapidly, by division; the bulbous kinds by offsets. Many kinds produce seeds which come true, although some of the species tend to sport. Seeds of some varieties germinate rapidly; others very slowly. In the solid bed of my cool house seedlings of several varieties are now springing up after having been carried a year in seed-pans, and then three months ago thrown out with the earth and given a chance under other conditions. This, by the way, is often a profitable precaution with all seeds of hardy plants which have failed to germinate after one has done his best with them in pans. To secure seed of some kinds it is evidently necessary to fertilize the flowers artificially, and the early-flowering bulbous kinds need protection under glass when in bloom; at least, *Iris reticulata* and similar kinds do not bear seeds when exposed in my garden.

The bulbous Irises require somewhat more care in cultivation than the other section. The conditions, however, are

modified by soil and climate, as is the case with many bulbs. It may be said in a general way that bulbous Irises do well in a good deep, well-drained, rich sandy soil free from humus or manure, and hereabout they should be planted in the warmest part of the garden. Excessive wet in winter seems to be their severest trial. The varieties of these bulbous species are becoming somewhat numerous, but many are still scarce, and experience as to the hardiness of some kinds is very limited. As yet I see no reason to doubt that all, except, perhaps, *I. alata*, can be grown out-of-doors if properly planted. At the same time, the best advice would be to plant the African Irises, *I. juncea*, *I. Tingitana* and *I. alata*, in a cool house. *I. juncea*, which is a variety with beautiful yellow-colored flowers, I have bloomed in the open without protection, but, while it still lives there, it is not to be depended on. Before going further I ought to warn the reader that I make no claim to be an authority on the Iris or its cultivation, and these notes are simply the impressions made on me as I have tried, with more or less success, to flower them, mostly by giving them their own way as nearly as I understood it.

For general garden-culture the varieties of *I. Xiphium* (Spanish Irises) and of *I. xiphoides* (the English Irises) are the most satisfactory, being easily managed, reliable and showy, while the bulbs may be had at an absurdly low rate from the Dutch bulb-growers. My personal preference is for the Spanish Irises on account of their more brilliant colors, but the flowers of the English Irises are larger, and furnish a perfect succession, coming on precisely as the others fade. The foliage of the Spanish Iris appears in early winter, and makes a gradual growth as the season advances, and does not seem to be affected by the hard conditions of that period. The flowers appear on stems about fifteen to eighteen inches high, and are in shades of yellow, brown, blue, white and orange in all quaint combinations. Like all Irises, if cut before unfolding, they may be brought into the house for decoration, and will prove more lasting than if gathered when fully opened. As these fade, the English Irises will unfold with another order of beauty, the colorings being mostly shades of purple and white. The pure white variety of this, *Mont Blanc* of the florists, is a chaste beauty. Varieties of both these groups seed freely, and give flowering plants in two or three years, which will naturally vary from the parent plants.

Before these Irises brighten the garden, however, the amateur in choice plants may enjoy the dwarf bulbous Irises like *I. reticulata*, or similar types. The first to appear is *Iris Bakeriana*, as it is first in beauty and hardiness. The first mild spell after the middle of January will wake it up in this latitude, and one can watch its quiet advance at every loosening of the frost, till it manages to unfold its charms in early February. It seems a marvel that such a fragile, high-colored flower should push its beauties with such audacity in the face of wild winter weather. The Snowdrops and Anemones will close up and seem to shrink while waiting for a better time, but not so this flower. It spreads wide open and frankly asks admiration, and be the weather what it may, it will endure a week of it. As a matter of prudence, however, the gardener should fix a pane of glass over it to guard it from snow or rain. This Iris is a trifle larger than *I. reticulata*, and has glaucous four-sided, channeled leaves (tetragonous the botanists call them), instead of the rounded leaves of the type. The colors vary; mine are a true blue on white, with rich royal purple markings. Next to this will appear *I. histrioides*, which seems to be the largest flower of the group, purplish blue, with dark purple spots and violet markings. *I. Histrio* has not flowered with me; it is said to be very similar to the above. Its bulbs are especially white and handsome.

I. Danfordiæ (Bornmulleri) is a light yellow Iris, which is still a failure here and a warning to me against planting bulbs in wet soil. *I. reticulata* major is an English seedling, with flowers of the same rich colors as the best forms of the type, but it is considerably larger, more vigorous and flowers earlier. The true *I. reticulata*, the little netted Iris, is a charming plant in the border, where it appears, however, to better advantage when grown in fair-sized colonies. It is perfectly hardy, but is improved by occasional lifting, and it may be said that all these bulbs should be examined every year to see that they are in good health. There are numerous forms of *I. reticulata*, the reddish purple being known as *I. Krelagei*, which is not attractive. The bluer forms are *Cœrulea*, *Cyanea* and *Sophonensis*, and Herr Leichtlin offers a few others quite unknown as yet in most gardens. *I. reticulata* forces very readily and does not mind a greenhouse temperature. In this situation its violet-like fragrance can be most thoroughly enjoyed.

F. N. Gerard.

Bacterial Disease of Beans.

ABOUT a year ago my attention was called to a disease of beans by a large commercial seed-house in the west. Samples of the affected beans were carefully examined, and only bacteria were found associated with the trouble. When planted, such beans quickly decayed, an occasional one only developing into a sickly plant. Previous to this a peculiar spotting of the pods of Lima Beans had been observed, and with this, too, only bacteria could be found, the leaflets at the same time showing large discolored blotches, which soon became brown and lifeless. While at the New York State Station at Geneva, Professor Beach called my attention to the same spotting and decay of pods and leaves of the common field beans, and informed me that he could attribute the work to nothing else than bacteria. Since then, during the fall months, visits have been made to large Bean-fields in New Jersey and Pennsylvania, with the result that this decay is found, not only wide-spread among beans, but common to all sorts, both bush and climbing, and in some places it ruins the crop.

From samples gathered upon one of these visits, the accompanying illustration has been made. The diseased spots show less plainly than in the real pods, because the contrast in color between them and healthy tissue is but slight. It was an easy matter to prove by inoculation that the decay of the Wax Beans is the same as that upon the Limas.

One of the most dangerous features in connection with this disease is that the germs are carried over from one season to another in the beans themselves. If it were possible to detect and thereby reject all affected seed, it would make matters easier. Many seeds are worthless at harvest-time, but others are only slightly infested, and it is these latter that do the most mischief. Great care should be taken with the beans used for seed; only the very best should be planted, and, if possible, purchases should be made of those who have not had any bacterial trouble in the field.

There is only one other Bean disease that might be mistaken for this, namely, the "pod spot," and this can be distinguished by its making deep pits, which are pinkish with spore-bearing pimples.

Rutgers College.

Byron D. Halsted.

The Propagation of Hardy Plants.

THE approach of another year reminds us that next summer's display depends largely on what is done now, while outdoor work is suspended. In every garden there is always more or less propagating to be done, whether by means of seeds, cuttings or grafting, and the next three months is the best time of the year to forward the work, more especially as we have now complete control of the temperature and atmosphere. Longer and hotter days means more air in the greenhouse and less moisture, and propagators well know how quickly cuttings wilt unless properly shaded and kept moist. Again, young plants started now gain strength with the advancing year and are in a good condition to set out when the proper season comes, and will, in many cases, flower this year.

We have just been grafting *Clematis paniculata*. The operation is simple enough, all that is needed being to splice the cion on the roots of another species, preferably *C. stans* or *C. Virginiana*. These are potted and plunged in a frame in the greenhouse, and they will start to grow in two weeks, and all will flower this year equally as well as seedlings three years old. Young grafted plants of this *Clematis* make excellent pot-plants when trained to stakes, for they flower from every leaf the plant makes, even from the level of the soil.

Perhaps the best way to propagate hybrid Roses is to obtain roots from some vigorous-growing species, such as *Rosa setigera* (the Prairie Rose), or *Rosa canina*, so much used in Europe as a stock for budding. Last year we took these roots and cut them in three-inch lengths and spliced single eyes of hybrid kinds on them. The kinds used were Ulrich Brunner, Heinrich Schultheis and Mrs. J. Laing. The first made growths

five feet long last summer, and the other sorts did almost as well, and they are the best plants we have now, out of several hundreds, for winter forcing. Cuttings taken at the same time and treated similarly are not more than half as vigorous as the grafted plants, and we experience no difficulty from suckers from the Brier roots as we do in plants budded in the orthodox way, for we take care to match the roots and the cion, using both of the same size, and it is difficult now to see where the union was effected, and there is no other way that I know whereby plants can be obtained of such strength in less than a year.

Those who wish to increase their stock of *Anemone Japonica* can readily do so now by cutting the roots in pieces, three inches long, and placing them in sand in a warm house. When they begin to grow, in a few weeks they may be potted up singly, and, later on, planted out. They will all flower this year if treated liberally as to soil and moisture, for this *Anemone* loves moisture, as all know who have grown it in pots for autumn decoration. In Massachusetts we lose half the flowers by frost when grown in the open ground. Seeds of

Fig. 106.—Pods of Beans showing Bacterial Disease.

perennials should all be sown as soon as obtainable now, as many, indeed most of them, take longer to germinate than the seeds of annuals do, and if the sowing is delayed until late in spring, a whole year is often lost in obtaining flowers. The one error of all others that is most common in seed-sowing, is that of sowing too thick. The plants either damp off wholesale in the seed-boxes when small, or, if they live, grow weak for want of space to develop perfectly, and when transplanted the loss is often great. It is far better to sow just as much as one can take care of properly. Plants, which have been stored for winter propagation, such as Phlox, Helianthus, Hardy Pinks, or others that are propagated from cuttings, should be encouraged to grow now and the cuttings should be taken as soon as possible, as they will root much more readily at this season than they will later.

South Lancaster, Mass.

E. O. Orpet.

Tagetes signata.—Among plants whose beauty is often overlooked because they are cheap and common is the delicate dwarf Marigold, known in seedsmen's catalogues as *Tagetes signata pumila*. Like other Marigolds, it is of the easiest culture, and becomes a compact bushy plant with finely cut leaves, yielding abundantly, and for a long time, its bright orange-yellow flowers, an inch in diameter. After giving a brilliant coloring to the garden for six weeks or more during the early autumn, a few of the plants, when heavy frosts appeared, were potted for indoor use. They appeared not to suffer from the change in the least, and continued to brighten our rooms for several weeks longer, although receiving very little care, and placed at a considerable distance from the windows. The delicacy of its foliage and the warm glow of its profuse bloom, together with its not unpleasant odor, made a most agreeable impression, so that the Marigold was the subject of even more comment and admiration than was its distant aristocratic relative, the *Chrysanthemum*.

State College of Kentucky.

C. W. Mathews.

Imantophyllum miniatum is one of the best plants for window gardens, yet it is seldom seen outside of greenhouses, probably because its merits are not more fully known. It has fleshy roots, Amaryllis-like flowers, and with us it commenced to bloom in October. The first flowers open near the ground and are nearly hid by the profusion of sword-shaped lustrous dark green leaves, some of them two feet in length, which surround the scape. Gradually the flower-stalk increases in height and is now eighteen inches long. It is crowned with nine large blossoms, which are a beautiful shade of salmon-pink. They are delicately fragrant, reminding one of the odor of Chinese Azalea. The plant has many buds still to open and it is in bloom quite three months of the year. The six petals of the flowers are alternately wide and narrow, and the interior of the flower-cup is a light lemon-yellow. These flowers are followed by ornamental bulbiform fruits, which do not often come to perfection under cultivation. Our specimen is on a stand close to a south window, where it gets some sun on every fine day, but is partially shaded by other plants. It has now sent up a new plant from a bulblet, which we shall separate and repot in the spring. *Imantophyllum* does not seem to require any rest and increases in beauty throughout the year. It needs abundant water and a rich compost of well-rotted manure and woods' earth.

The Black Knot.

To the Editor of GARDEN AND FOREST:

Sir,—The passage of a law in New York state to enforce the eradication of the black knot that infests Plum and Cherry trees is notable mainly for its excellent purpose. The law is too circuitous to be easily enforced. On a petition of five freeholders a commission may be appointed, with power to act, in any town. But it will rarely occur that five complainants and petitioners will appear. It will hardly be worth while for one town to be stringent in the clearance of the pest so long as it grows freely in the adjoining township.

I have found but little difficulty in keeping my trees clear, except that it constantly reappears on that side of my land adjacent to a very slovenly kept orchard and lawns. From this side the spores enter my grounds and keep up constant warfare.

There is great difference in the susceptibility of different varieties of Plum-trees to this disease. Bleecker's Gage, or Lombard, and the old English Horse Plum, or Large Damson, a plum now seldom found, and Magnum Bonum are peculiarly susceptible. Shropshire Damson, Washington, Coe, Bradshaw, Reine Claude are among those very little susceptible. Green Gage may be classed midway between the others named. I have found it possible by watchful care and cutting to keep all varieties in good order except the Horse Plum and Bleecker's Gage. These I find it necessary to cut down after a few years, and replace with young trees. But as both varieties are very rapid growers, this is not a serious inconvenience.

Three years ago a form of the knot appeared on my native Bird Cherries, used as ornamental lawn-trees. The nature of the knot in these cases is longer, and folds in the whole twig or limb. It is far more difficult to cut away. In the case of the Plum-trees I send a trained man over my trees in the spring, and again as soon as the crop is removed in summer. He cuts knots out, and, if needful, cuts off limbs. His instructions are to cut smooth, and two inches above and below a knot, as

far as the black line appears under the softer layers of wood. But the damage to my lawn Cherries is disastrous.

Persistent care will surely keep a Plum-orchard in excellent health. I have one hundred bearing trees, and am willing to offer a reward for every knot found uncut. Our plum crop is in great demand, and generally very remunerative. Whether any law can be devised to take the place of public intelligence and foresight is doubtful. One thing is certain, we must educate ourselves to a thorough understanding of our fungous and insect foes, or be beaten in the strife, whatever our laws may be.

Clinton, N. Y.

E. P. Powell.

The Spirit of the California Fruit-growers.

To the Editor of GARDEN AND FOREST:

Sir,—The annual conventions of the California fruit-growers are always interesting and important. From 250 to 500 of the thirteen or fourteen thousand orchardists of the state assemble and devote a week to reports and discussions. Two such conventions are held each year, each time in a different district; a monthly meeting takes place in San Francisco, and one in Los Angeles; and the fruit-growers also have county, township and small district societies or clubs. The entire body of fruit-growers is registered, and its effective organization extends to every part of California.

In the recent convention the high literary quality of many of the papers read, was very noticeable. University graduates, ex-bankers, retired merchants and professional men of the first rank who have taken up fruit-culture as a life-work, are fully capable of going straight to the mark. Every great convention of the horticulturists here is characterized by thoughtful addresses, which are masterpieces in their way, full of special knowledge, and always practical.

One of the best fruit-growers said to me recently, "We, who raise the fruit, are trying, at any cost, whatever looks feasible, and we report to each other. We want more science of the higher kind, no matter how many years or how many dollars it takes, and we will advocate every expenditure on the part of the state and the higher institutions of learning. We want to educate men of science here, we want to support them when they come, though the results cannot be measured in dollars and cents."

There are many of the leaders of the conventions who have taken up the business in this broader spirit. They not only discuss prices and markets, stocks, varieties, and the constantly multiplying details of horticulture, but they appeal to the higher intelligence of their class, and point out the larger relations of the problems involved. The fruit-growers, for instance, are becoming a unit in favor of the maintenance and protection of the forests, and the last convention recommended the passage of Senator Paddock's bill. To quote from the opening address of President Elwood Cooper, of Santa Barbara, if the fruit-growers continue to maintain an "unselfish interest in the general welfare," they will "eventually become a controlling interest in state affairs." "While our especial purpose," he says, "is to interchange ideas, and discuss fruit problems, we are developing other interests, and effecting more important results than even the successful culture of fruits." This spirit, which pervaded many of the convention addresses, appears to me full of happy promise. It really makes very little difference to California's permanent interests whether she takes a few more or a few less of the coming Chicago honors, but it makes all the difference in the world whether the informing spirit of her horticulture fosters higher science and the nobler interest of the commonwealth.

Illustrative of the practical side of the recent convention's work I mention the following items: The fruit-growers asked the state to appropriate \$20,000, to be spent during four years in experimenting with all the obtainable species of friendly insects that will hold in check or destroy the enemies of plant-life. The convention discussed this subject, and every phase of the long difficult fight against injurious insects; it discussed markets, and fruit-unions, in many forms; it suggested the need of a permanent Commissioner of Horticultural statistics; it even took up the ten-block system of numbering country houses and farms, which originated in Contra Costa County and is a great convenience to all concerned. There was talk about roads, village improvement clubs, gardens, and many other topics, treated briefly and well. There were also excursions to particular orchards, to see the methods of management.

The one fact upon which I wish to put emphasis is that these California conventions are growing in importance to the community at large. They have increased in size every

year, but they have gained even more in "average ability" of their members and in dignity of behavior. Their committees are eminently able in these days to urge desired reforms upon legislatures and changes in freight-rates upon railroad companies. The politicians of the cheaper sort are beginning to be afraid of the fruit-growers, who come straight from their orchards twice a year, often with their wives to help, and sit in council with members from every other district in the state.

Early and Late Strawberries.

To the Editor of GARDEN AND FOREST:

Sir,—The account of Mr. Blacknall, on page 570, in his efforts to get the ideal early Strawberry by cross-fertilization, recalls my efforts to obtain a late Strawberry by the same methods. Until a few years ago, only the very largest of Maine strawberry-growers shipped their crops to Boston and New York, and even now this industry is young and growing slowly because of irregular shipments, high commissions, and the damage to the fruit in transit.

The season for cheap strawberries in New York and Boston begins about May 15, and extends to July 4, after which raspberries and blackberries are in the market. In Maine, however, our Wilson Strawberries begin to ripen about June 20, and the Sharpless on July 4, so that we have strawberries from the vine as late as July 15. I find that by setting plants in low, mucky land, covering them deeply with straw and brush, and keeping them covered until June 1, or later, the ripening can be delayed until nearly August 1, when I have a monopoly of the big cities.

What we need here is a late, rank-growing, hardy plant, with fruit the size of the Sharpless, the color and firmness of Wilson's Albany, and as prolific as the Crescent. In my efforts to get such a plant, I have moved fully 2,000 seedlings, and of these I am wintering but seventeen. It is a slow, hard task. The rank-growing plants, as a rule, are not hardy, while the dwarf varieties are too early for my use. A type that is almost perfect when in pots takes to sporting and goes back to its original form as soon as set out in the ground. And so I have thrown away my pets one by one until not a score remain. Meanwhile, I shall keep crossing and experimenting until I get the right kind, after which Mr. Blacknall's earliest and my latest will furnish the people of New York, Philadelphia and Boston with cheap strawberries for six months every year.

Brewer, Me.

Desecration of Natural Beauty.

To the Editor of GARDEN AND FOREST:

Sir,—I wish to thank you for the editorial article on the Defacement of Scenery, which appeared in a recent issue of your paper. Thoughtful persons have long noted and deplored the rapid destruction of the landscape beauty which the slow processes of nature have been unfolding through centuries of growth and change, but they have kept silent because protest seemed useless. It seems now that the desecration of high, if not of holy, places, by the paint-brush of the advertiser, has awakened some indignation; and if this indignation has found a louder expression than that which has been called forth by the blasting work of the railroad, the oil-well, the charcoal-furnace or the mine, it is only because there seems some hope of redress in the first case, while the widespread desolation from other causes has appeared to be the costly, but inevitable, sacrifices which the spirit, or the demon, of material progress demands.

Your suggestion that our heritage, the beauty of the world, is a trust for coming generations, places the matter on its proper footing. "Man cannot live by bread alone," and the material prosperity gained by the destruction of pure and noble forms of beauty may prove in the end a national calamity. It certainly will be such a calamity if it is true that landscape beauty is a vital necessity to the mental and spiritual health of a people. In a thoroughly enlightened society the conservation of natural beauty would be regarded as a national duty just as truly as the protection and development of any other natural resource which makes for the public wealth or health—an obligation as binding as that which leads a government to keep its river channels clear or its harbors safe or its forests productive. Governments build libraries and establish universities and galleries of art to cultivate men's higher nature. They have no right to permit the destruction of what the Almighty has already prepared to serve the same high purpose.

Orange, N. J.

New Cyripediums.

To the Editor of GARDEN AND FOREST:

Sir,—The following hybrid Cyripediums have recently flowered for the first time at the United States Nurseries, Short Hills, New Jersey:

CYRIPEDIUM BARTETI ANGUSTUM.—This distinct variety was obtained by crossing *C. barbatum* Warnerii with *C. Insigne* Kimballianum. Growth very compact; leaves narrow, three to four inches long, pointed. The dorsal sepal long, narrow, yellowish green at the base, shaded and spotted with brown; petals narrow, purplish at the ends; lip long and narrow, shaded heavily with brown.

CYRIPEDIUM NIOBE SHORTHILLENSE.—A beautiful and distinct variety of a great merit; flower large, well-proportioned, having the vinous purple lines reaching nearly the top of the dorsal sepal, and washed over on the sides; the yellowish green portion in the lower part is also much brighter. The sepals and the lip are very dark, brown-purple, with a broad mid-vein of vinous purple through the petals.

CYRIPEDIUM NIOBE MAGNIFICUM.—Differs from the type in its large dorsal sepal, which is pure white with the exception of the purplish line through the middle, and the brown and green portion in the lower part, as in *C. Spicerianum*. The sepals and the lip large, color the same as the type.

Short Hills, N. J.

Joseph Manda, Jr.

Plantago media.

To the Editor of GARDEN AND FOREST:

Sir,—It may be of interest to some of your readers to know that the Plantain mentioned in your issue of November 16th, page 550 (*Plantago media*), has been growing in Providence for at least three seasons. It was collected by me in 1890, and specimens of that date are in Brown University Herbarium. I secured a few more specimens at the same station last June.

If memory serves me correctly, one of our local collectors obtained specimens of this same Plantain in 1890, and I had always supposed he sent specimens to Harvard Herbarium at that time until I read the letter in your columns.

Providence, R. I.

J. Franklin Collins.

Meetings of Societies.

The Kansas State Horticultural Society.

THE twenty-sixth annual meeting of this society was held at Winfield, which is in Cowley County, one of the southern tier of Kansas counties, just east of the Arkansas River. It is one of the best fruit-growing regions of the state, and its productive capacity is only just beginning to be understood. Some of the leading points brought out in the papers and discussions are herewith given:

APPLE ORCHARDS.—For the eastern and northern portion of the state the uplands were considered preferable to bottom-lands for orchard purposes, and northern and eastern exposures were recommended, since the trees in such locations are less subject to sun-scald and the influence of heated winds during the drier months. In the Arkansas valley, on the contrary, the bottom-lands were recommended for orchards, there being along the Arkansas River and its tributaries much land where the sub-flow water is reached at a depth of only a few feet. It was believed that Apple-tree-roots penetrated deep enough to drink this moisture, and growth was, therefore, much greater and the trees longer-lived. Thorough and deep preparation of the soil was advised, and where the subsoil is of a stiff, refractory character, such as is found underlying much of the prairie country, the use of the subsoil-plow found many advocates. The too common practice of setting the tree in a hole dug in the hard ground, instead of loosening up the whole area, was believed to cause the early death of many young trees. The discussions brought out the fact that several large commercial orchards had been planted in this section, one of over 600 acres in Greenwood County ranking second only to the great Wellhouse orchard of Leavenworth County, with its 75,000 trees. Growers in the eastern counties have in years past found a considerable market in the western portions of the state, but their sales are cut off more and more each year by the crop from younger orchards further west. First the home-demand is supplied, and then the fruit finds its way to the west, till there are now few localities in the eastern half of the state not supplied with home-grown fruit in a favorable year, and a partial supply is grown well out to the one-

hundredth meridian. There seemed to be little apprehension, however, as to markets for Kansas apples. The north-west states and the mining regions of the mountains will long make a good demand, and it was pointed out that there is a growing inquiry in the south for long-keeping winter apples.

THE BEST VARIETIES.—Ben Davis seemed to stand first in the esteem of market-growers as an apple for profit. The free growth of the tree, its hardiness and abundant yield of large and handsome fruit are strong points in its favor. Missouri Pippin ranked a good second, as it comes into bearing early and yields enormously. Gano and York Imperial are being planted largely, but the test of time is needed before growers will plant orchards of these sorts with the same confidence which they feel in the two first-named. Duchess of Oldenberg was mentioned favorably for its extreme earliness, being the first on the Chicago market. Keswic Codlin, a later apple, was regarded as worthy of more attention. Jonathan and Wealthy were considered profitable late autumn sorts, although they did not carry far into cold weather.

THE YEAR'S YIELD.—From the fruit reports it was evident that such a general failure had never been known before of apples, pears and peaches. Except in an orchard here and there, in some exceptionally favored and sheltered locality, nothing like a crop was produced. Although in nearly every section of the state the bloom was abundant and a full crop often set, nearly all the fruit dropped before it reached any size. The scab prevailed to an extent heretofore unknown, and the consequent loss of foliage in most cases was great and ruinous. By those who had given the subject the most careful study it was believed that the premature dropping of so much fruit was due to the low vitality caused by this disease. More of Rawles' Janet apples were produced than of any other sort. This variety blooms later than the average and seemed in a measure to escape the unfavorable weather. In one county a young orchard of Canada Pippins, or White Pippins, had borne a handsome crop and proved very profitable. Plums and cherries, except in a few cases, had failed. The short strawberry crop suggested the rejection of varieties with soft, watery berries, and the Robinson, a Kansas seedling, was recommended by a good authority as the best all-around berry. Blackberries in the eastern counties gave a full crop; further west they failed. Snyder seemed to be the favorite sort. Of black Raspberries, Nemaha, Progress, Palmer and the Kansas were commended by shippers, while Souhegan was a general favorite for near markets and home use. Thwack and Cuthbert were the favorite red varieties, but this fruit is not very generally grown. Gooseberries, to the few who had tried them, gave good returns, and Currants, when in a cool place, sheltered on the south, yielded well. Grapes were nearly a full crop and the quality was unusually good.

IRRIGATION.—For the central and western counties the use of water, wherever available, from spring, reservoir or wind-pump, was advocated by the most enterprising gardeners, to tide over periods of drought. The fact was pointed out that, in many counties, there are numerous springs running to waste, and often injuring the land below them, where, if properly piped and distributed, they might bring a handsome income from vegetables and small fruits. Celery, which is only profitable when grown as a late crop, so that it can make its growth after the dry, hot season, can be successfully cultivated with partial irrigation. It is now grown in this way to a considerable extent, and the home product easily holds the market against that from Kalamazoo. One grower, by the way, whose young plants had been largely destroyed by the tarnished plant-bug, had succeeded in routing the enemy with a very strong kerosene emulsion. This was found to destroy many of the plants, which rotted at the heart. Later on he discovered that injury from the emulsion could be prevented by turning a hose on his plants and washing them freely with clear water.

GROWING POTATOES.—An interesting fact was presented in a report upon potato-culture, as to the value for seed of potatoes grown as a second crop. As ordinarily planted here, the potato matures in July or August, and is apt to sprout and make second growth, as it has a long season yet to lie in the ground or in a warm cellar before cold weather. Such potatoes come out in the spring soft and shriveled from much sprouting, and lack the vitality necessary to a vigorous growth. By planting early sorts, they may be dug in July, and, after a few days' exposure to the light, can be planted for a second crop. It is recommended not to cut them for this purpose. This second crop is left in the ground as late as possible, and yet escapes freezing. While the crop is usually light, the quality is remarkably fine, and these tubers come out in the spring as

firm and free from sprouts as when put in the cellar. Planted by the side of ordinary seed, the difference in vigor and yield is remarkable, the unusually high percentage of choice table potatoes being a great inducement to the market-grower.

A discussion of this paper revealed the fact that this method of growing seed had been followed in a quiet way by several old gardeners in the state for some time, and that the Experiment Station had the report of three years' work in this line ready for the press. Of course, the idea was not new, but the application of it to Kansas gardening was a revelation to many.

THE PROPAGATION OF TREES.—Under the subject of methods of propagation a veteran nurseryman exhibited two-year-old Ben Davis trees worked on pieces of seedling-roots of various length, with samples of the grafts as made. There were whole-root grafts so long as to require a deep trench to set them in, and "piece roots" in sizes down to an inch in length. The sample trees showed little difference resulting from these different methods, all being furnished with abundant roots from the cion, and making a tree practically on its own roots. The best trees shown were from cions eighteen inches long grafted on pieces of root two inches long. Here the additional foliage secured at the start seemed to excite more vigorous root-growth, and a strong, well-balanced tree of unusual strength, both of root and top, was the result. A special committee, appointed to report upon methods of propagation, gave it as their opinion that no advantage, but rather a positive detriment, resulted from the use of whole root-stocks for Apple-trees, and the practice of certain nursery companies in selling such trees to uninformed persons at exorbitant prices was severely condemned.

How to beautify the farmer's home and surroundings was one of the subjects debated, and a very careful study of plans for remodeling old homes was presented by Professor J. D. Walters, of the Agricultural College, who showed that in the hurry of opening up a new farm in the west the buildings are too often placed here or there with little thought as to a general plan or the convenient and tasteful arrangement of the whole. Some possibilities in rearrangement and the bold strokes often necessary to get unsightly barns and yards back from the road were very graphically set forth in this paper.

Short Studies in Botany for Children. By Harriet C. Cooper. New York: Thomas L. Crowell & Co.

Each one of the thirteen chapters in this little book is devoted to a description of one of the natural orders of plants; that is, the principal characters of the Mint family, the Pine family, the Pulse family and the rest are explained in simple but accurate language, so that a bright child who goes through these pages, under the direction of some careful teacher, will acquire a considerable rudimentary knowledge of botanical science. The best way to begin the study of botany is to study the plants themselves, and this book will be helpful, so far as it is used in connection with living or dried specimens, to encourage original investigation. It may be questioned whether the shadowy persons who carry on the dialogues in the book add much to its interest. The real plants need no accompaniment of fictitious little girls who are little more than empty names. But the merit of the book is, that the descriptions are precise, and the points of fundamental resemblance which unite the various genera into families are carefully brought out and are treated in such a way as to suggest the most useful lines of study.

Old Concord: Her Highways and Byways. By Margaret Sidney. Boston: D. Lothrop Company.

This is a new and enlarged edition of a book published four years ago, and the fifty or more illustrations of points of historic interest which it contains, give an attractive view of the more striking features of the old town. The gossipy text hardly equals in merit the pictures, many of which have a genuine artistic value; but very little that is novel or fresh can now be written of Concord. Scenes once described by Hawthorne or Thoreau can hardly be depicted more vividly by other pens. But one never tires of reading of the famous old town, with its memories of Revolutionary times and its homes of great thinkers in later days, and this beautiful volume cannot fail to bring genuine pleasure to those who have visited Concord, by reviving memories that slumber, and to those who have never trodden its historic highways and byways, by giving them a clearer idea of its appearance and suggestions of its singular charm.

Notes.

The Irish Land Commission is planting large numbers of forest-trees on the west coast of Ireland.

The Ice Crop is the title of a little book published by the Orange Judd Co. which gives explicit instructions for cutting, storing and handling ice, the construction of houses for refrigerating and cold houses for keeping fruits and other perishable substances. It contains 114 pages and is profusely illustrated.

Belgium has two Government establishments where horticulture is taught, one at Ghent, with an average attendance of forty-four pupils, and one at Vilvorde, with an average of thirty-eight, and besides these the Government subsidizes six other institutions in which tuition is given and experiments in horticulture are carried on.

On the fringe of the Colorado desert, near the old railroad station of Seven Palms, horticulturists have proved that the production of early fruits is possible. This year oranges from this place were in market as early as the 20th of November, while figs, pears, apricots, small fruits and vegetables ripened especially early.

The order for a forest-reservation in San Bernardino County, California, which will protect the watershed of the Sierras for fifty miles, is giving delight to the horticulturists of southern California. The new reservation includes the sources of all the large irrigation systems of that part of the state, and hereafter the Sheep-men will be prevented from starting fires in the protecting forest.

One is rather surprised to find Yuccas in bloom out-of-doors in the last days of December, but visitors to Central Park have been favored with such a spectacle this year. The plants that have flowered are labeled *Yucca recurva*, but look as if they might be some form of *Yucca gloriosa*. The cluster of long green leaves, without any filaments, starts from the summit of a stem about two feet high, and the flowers, although they look rather limpy and unhappy in the frosty air, are fairly well opened.

At Walter's Station, on the Southern Pacific Railroad, in the desert, a hundred miles west of Yuma, a boring of five hundred feet has found a supply of artesian water, which rushes to the surface with a strong flow. It is all that could be desired in clearness, coldness and quantity, and, if the flow proves permanent, this will mean that the desert is to blossom like the Rose. These arid lands, although at present worthless, are rich in the elements of plant-food, and only need water to produce abundant orchard and field crops.

In a recent description of Penrhyn Castle and its grounds, in North Wales, it is said that many plants, which are usually grown in greenhouses, are standing in sheltered nooks about the castle, where they flourish with but little protection. Among them are *Agapanthus umbellatus*, *Lapageria rosea* and a huge Bamboo, *Arundinaria falcata*. It might be supposed that, in such a favored spot, Palms, which flourish in northern China, would be at home, and, as a matter of fact, a magnificent pair of *Chamærops Fortunei* has stood out for years.

In speaking of the Globe flowers, the London *Garden* says, that occasionally, in England, old-established plants give a few flowers in September and October. We have found that it is the general habit of the Mountain Globe flower (*Trollius Europæus*) to bloom with some freedom through the late autumn months, when the bright yellow globes, an inch or so in diameter, are very attractive. These Globe flowers deserve a more prominent place than has been given to them in our hardy gardens. Their roots like a cool, well-drained soil, but one where moisture can be reached.

Since the latter part of November, Mandarin oranges, grown in Japan, and imported by steamer, have been selling by the wagon-load on the streets of San Francisco at ten cents a dozen. The fruit is fair, not fully ripe, but palatable and easily prepared for eating. The very best of these oranges are carefully wrapped, singly, in strong white paper, upon which is printed, in legible English, "This is a genuine Mandarin orange, imported direct from Japan. Any persons wishing to obtain the trees from which such oranges are grown, may apply to —". This shows a shrewdness in advertising which may give a hint even to Yankee enterprise.

A correspondent of the *Gardeners' Chronicle* notes the fact that this year has passed without the celebration of the cente-

nary of the *Camellia*, which, although it had been introduced earlier, flowered for the first time in Europe in 1792. It is also suggested as a matter worthy of historical research that some one should find out how long the various single-flowered varieties were in cultivation before the first double flowers appeared. It is only a few years since the Bolivian *Begonia* and its allied species were introduced and double-flowered tuberous varieties began to appear as if by magic. On the other hand, the Persian *Cyclamen* has been generally cultivated for a much longer period, and yet we rarely see a plant which bears double flowers.

Rev. C. Wooley Dod writes to the *Gardeners' Chronicle* that having noticed among some plants of *Chrysanthemum maximum* a seedling with abnormal leaves and habit he potted it to flower in the greenhouse. It has now produced a yellow flower new to the writer, and he infers, with some reason, that the plant is a hybrid between *C. maximum* and *Anthemis tinctoria*, as these two plants were near together. Mr. Dod adds that in his garden, where accidental seedlings are usually allowed to flower where they come up, spontaneous hybrids between distinct species are of common occurrence. If this new plant is a hybrid between members of different genera it is the second probable case of the kind in Mr. Dod's garden, the first having been a supposed hybrid between *Chionodoxa Lucilliae* and *Scilla bifolia*.

We are glad to know that a report on Nuts and Nut-growing is in course of preparation by the Department of Agriculture, under the direction of Mr. H. E. Van Deman, the pomologist. Several very large Chestnuts have, within a few years, been brought before the public, among them the Ridgely, which originated near Dover, Delaware, and was once thought to be an American variety or cross between our native Chestnut and the European. Mr. Van Deman is convinced, however, that this is a seedling of purely foreign stock, just as Paragon and Numbo are. These three kinds bear while very young, and they bear abundantly, and although the flavor is not equal to our own wild Chestnuts, they are very good when cooked. It is to be hoped that more attention will be given to varieties of our native Chestnuts that are particularly large-sized, so that, by careful selection and propagation, we can have Chestnuts which, in addition to considerable size, will have the unequaled flavor of our native nuts.

In the issue of *The Tribune*, of this city, for December 25th, Professor Charles H. Peck, of Albany, Botanist of the State of New York, gives some account of a Mushroom which he pronounces a new species. This Mushroom has been cultivated for some time by a market gardener whose place adjoins that of Mr. Charles A. Dana, at Dosoris, Long Island, and Mr. William Falconer, Mr. Dana's gardener, forwarded a specimen to Professor Peck. A few weeks later Mr. Falconer found a specimen on Mr. Dana's grounds, and sent that also, and from an examination of the two, Professor Peck has established a new species which he calls *Agaricus subrufescens*. The stem is thicker toward the base and is generally longer than that of the common Mushroom. The collar about the stem is thicker, and on the under surface is covered with little flocculent scales. The spawn is coarser and more stringy. Its scales are at first white, the cap is grayish white, often with a reddish tinge and obscurely spotted. The merits of the new plant are said to be that it is strong and hardy, and can be profitably raised in the summer; that the Mushrooms appear from ten days to a fortnight sooner after planting the spawn than is the case with the ordinary species.

Catalogues Received.

J. E. BOLLES & Co., 336-342 River Street, Detroit, Mich.; Wrought Iron Fences, Grills, etc.—A. BLANC & Co., Philadelphia, Pa.; Illustrated Catalogue of Rare Cacti, Bulbs and Tubers.—S. W.
